Aprotinin is a direct enzymatic inhibitor of plasmin and has other protease-inhibiting properties that confer its antiinflammatory and antikallikrein effects. However, aprotinin was notably associated with increases in post-CPB creatinine values and other adverse organ system outcomes in large-scale observational trials.[119] When a randomized prospective trial showed an increase in mortality in the aprotinin group, despite a reduction in bleeding, the drug was removed from the global market.[120] Although the causes of death in the aprotinin-treated patients were not found to be related to thrombosis or other drug-related effects, aprotinin was rendered unavailable for commercial use for years after publication of this study. The decision to remove aprotinin from clinical use was revisited on reevaluation of these study data, and aprotinin has been reintroduced in Canada and other countries specifically for use as labeled in CABG surgery.

Hypercoagulable States. The use of antifibrinolytics has become common in cardiac operations that require CPB. The use of antifibrinolytic drugs and prohemostatic drugs and blood products to treat bleeding has brought to light the risk of thrombosis in CPB, during which feedback mechanisms are critical and homeostasis is perturbed. All patients incur this risk of thrombosis as consumptive coagulopathy increases, but the risk is greatly increased in patients with congenital or acquired thrombophilic states.[121] These states may be important in view of current practices that involve pharmacologically inhibiting fibrinolytic pathways in cardiac surgical patients.

The factor V Leiden (FVL) mutation is the most common inherited thrombophilic disorder; its prevalence is 3% to 7% in white populations.[122,123] Mechanistically and clinically, FVL has been implicated in thrombotic complications in cardiac operations, most often those involving a period of circulatory arrest and the use of antifibrinolytics.[124] In a review of FVL mutation, Donahue gave the following summation and recommendations[121]:

- Cardiac surgical patients who are heterozygous for the FVL mutation bleed less than do noncarriers.
- The risk of early graft thrombosis may be increased in patients with FVL deficiency.
- The use of antifibrinolytic drugs may increase thrombotic risk in patients with FVL.
- Anecdotal evidence suggests that in patients with FVL mutation who are exposed to deep hypothermic circulatory arrest, antifibrinolytics increase thrombotic risk.

Cardiac Surgical Patients Taking Anticoagulant or Antithrombotic Drugs. Antithrombotic therapy in cardiac surgical patients has many roles and applications. Patients with ischemic heart disease can be managed short- or long-term with pharmacologic drugs that may include aspirin, AT inhibitors (heparins), direct thrombin inhibitors, or an array of platelet inhibitors (adenosine diphosphate [ADP] receptor inhibitors and glycoprotein IIb/IIIa [Gp IIb/IIIa] receptor inhibitors). Patients with a history of peripheral vascular disease, valvular heart disease, or low ventricular ejection states can similarly be managed with some form of antithrombotic therapy that may also include warfarin. Frequently, patients arrive for surgery while receiving multiple antithrombotic medications. Thus, postoperative bleeding is a common but challenging complication of cardiac surgery, especially when the bleeding risk posed by CPB itself is considered.

The use of percutaneous coronary interventions such as angioplasty and intracoronary stent deployment for ischemic heart disease has led to the use of antithrombotic medications to maintain stent patency and to prevent stent thrombosis. The American College of Cardiology and AHA (ACC/AHA) initial guidelines for percutaneous coronary intervention recommended (on the basis of class I evidence) the use of both aspirin and clopidogrel for at least 1 year after drug-eluting stent placement.[125] However, percutaneous coronary intervention data with the second generation drug-eluting stents indicate that shorter periods of dual anti-platelet therapy are equally effective in preventing in-stent thrombosis, and thus allow for earlier cessation of a single anti-platelet agent after 6 months.[126] This opens the door for interventions and surgical procedures to be performed sooner and with less risk of bleeding. The administration of thienopyridine antiplatelet drugs in addition to aspirin increases the risk of bleeding after cardiac surgery[127]; however, it is unclear whether aspirin alone increases this risk. Abundant evidence (mostly level B evidence from small, retrospective, nonrandomized studies) suggests that the ADP receptor antagonist clopidogrel (Plavix) has been associated with excessive perioperative bleeding in patients who undergo CABG.[128] This trend has even been reported in the OPCAB population, although not consistently.[129] Earlier recommendations included a 5- to 7-day delay after discontinuation of clopidogrel in patients who require CABG. However, guidelines[77] suggest that a 3-day delay may be sufficient to lessen bleeding risk and provide safe outcomes.[130] It is likely that a 5- to 7-day delay is not necessary, but some interval between the discontinuation of clopidogrel and CABG is supported by the available evidence.

Patients with a history of Gp IIb/IIIa receptor blockade as a part of their acute coronary syndrome management are at risk of increased bleeding and blood component use when they are given abciximab, especially within 12 hours of cardiac surgery.[131,132] Shorter-acting Gp IIb/IIIa receptor antagonists do not seem to increase bleeding or adverse outcomes and in fact may improve myocardial outcomes when Gp IIb/IIIa blockers are in use.[133] The interval between the discontinuation of antiplatelet therapy and cardiac or noncardiac surgery is critical to preventing thrombotic events without increasing the risk of bleeding. These decisions regarding the cessation of therapy can be guided by knowledge of drug pharmacology and testing of antiplatelet drug efficacy.

Enoxaparin, a low-molecular-weight heparin, increases transfusion rates and the risk of surgical reexploration when it is used in association with CPB.[134] Low-molecular-weight heparin may also decrease heparin responsiveness.[135]

Patients who present for cardiac surgery with residual warfarin effects may benefit by having enhanced anticoagulation during CPB. Postoperatively, if excessive bleeding is noted and is confirmed by hemostasis testing, factor replacement can be performed with blood products or pharmacologic prothrombin complex concentrates (PCCs).

Patients with atrial fibrillation may be maintained on new antithrombotic therapeutic drugs, direct oral anticoagulants (DOACs) that include thrombin inhibitors (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban). These drugs are potent and long-acting, and they have no antidote, so one would expect that treating cardiac surgical patients with these drugs would increase their bleeding risk. When compared to vitamin K antagonists, the DOACs have similar thromboprophylaxis efficacy yet fewer bleeding complications.[136] An additional benefit is that DOACs have a predictable pharmacodynamic profile and routine monitoring is often unnecessary. Routine monitoring tests such as the INR and aPTT do not even accurately assess anticoagulant activity of the DOACs and thus a thrombin time or a direct measure of anti-Xa activity would be considered more accurate.[137,138]

In summary, patients who present for cardiac surgery with preexisting, pharmacologically induced inhibition of the hemostatic system may have undesirable post-CPB bleeding. The diagnosis and treatment of this complication should be the same whether the derangement is a function of CPB itself, coexisting pharmacologic inhibition, or both. The management and treatment of persistent postoperative bleeding are discussed in the section on problems in the postoperative period.

INDUCTION OF ANESTHESIA AND THE PREBYPASS PERIOD

Premedication

The anesthesiologist should ensure that appropriate premedications are administered with a sip of water on the morning of surgery. With a few exceptions, patients should receive their usual long-term medications, particularly β-adrenergic blocking drugs, on the day of surgery. The clinician should be aware that ACE inhibitors (ACEIs), if administered on the day of surgery, may increase the patient's propensity for hypotension.[139] With respect to aspirin, it is recognized that aspirin administration in the early postoperative period may reduce the risk of ischemic complications after CABG surgery.[140] However, patients who receive aspirin immediately preoperatively may have more mediastinal bleeding and greater transfusion requirements. A consensus statement published by the STS recommends that low-intensity antiplatelet drugs (e.g., aspirin) be discontinued before cardiac surgery to reduce patients' blood transfusion requirements, but this should be done only in purely elective cases in patients without acute coronary syndromes.[76]

However, drugs that inhibit the platelet P2Y12 receptor should be discontinued before operative coronary revascularization (either on-pump or off-pump), if possible.[76] The interval between drug discontinuation and operation is determined from the drug's pharmacodynamics but may be as short as 3 days for irreversible inhibitors of the P2Y12 platelet receptor. POC tests are available to measure platelet ADP responsiveness. POC tests that show normal platelet ADP responsiveness after administration of an initial dose of clopidogrel indicate P2Y12 resistance with as much as 85% specificity.[141,142] This is called "high on-treatment platelet reactivity." Flow cytometry may be more specific in diagnosing the degree of platelet inhibition, but it cannot be measured at the point of care.[141,143]

The prospect of undergoing cardiac surgery provokes anxiety in most patients. Furthermore, the insertion of intravenous and arterial catheters is painful and must be done before anesthesia is induced. The resultant anxiety and pain can lead to undesirable sympathetic stimulation, with consequent tachycardia and hypertension. The first step in preventing this cycle is thoroughly explaining the anticipated anesthetic techniques and procedures to the patient. Premedication with a narcotic or anxiolytic drug, or both, to mitigate pain and anxiety is usually indicated before the patient is transported to the operating suite. Supplemental intravenous drugs—commonly midazolam and possibly fentanyl—are usually necessary during radial artery cannulation before anesthesia is induced. However, in patients with low CO secondary to congestive HF (CHF), sedation should be performed judiciously to avoid myocardial depression and resultant hypotension. Moreover, in patients with significant pulmonary hypertension, oversedation and respiratory depression leading to hypercapnia or hypoxia must be avoided.

Induction of Anesthesia

In preparing for induction, the clinician should have the following drugs immediately available: vasopressors (e.g., phenylephrine, ephedrine, calcium chloride, readily available vasopressin), one or more inotropes (e.g., ephedrine; epinephrine; readily available norepinephrine, dopamine, or dobutamine), one or more vasodilators (e.g., nitroglycerin, nitroprusside, nicardipine), an anticholinergic drug (atropine), antiarrhythmic drugs (e.g., lidocaine, esmolol, magnesium, amiodarone, adenosine), and heparin.[144] Commonly administered drugs should be drawn up and ready for administration by bolus or infusion, as appropriate; agents that are used less commonly should be readily available in the operating room. Protamine should be readily available, but many institutions require that protamine be stored in unique packaging or at a separate, nearby location to prevent inadvertent premature administration.

Furthermore, the selected antibiotic should be ready to administer according to Surgical Care Improvement Project guidelines. The STS recommends a cephalosporin as the primary prophylactic antibiotic for cardiac surgery; the drug should be administered within 1 hour before incision.[145] In patients who are allergic to penicillin, vancomycin is administered within 2 hours of incision. Finally, antifibrinolytic drugs are commonly used to minimize bleeding and the need for transfusion during cardiac surgery. The most commonly used antifibrinolytic drugs are the synthetic lysine analogues TA and EACA; both reduce total blood loss and decrease the number of patients who require blood transfusion during cardiac procedures.[76]

Anesthetic drugs and techniques for inducing anesthesia should be selected with consideration of the patient's cardiac pathophysiology and other comorbid conditions. No single "recipe" can guarantee hemodynamic stability during anesthetic induction. Hypotension may result in a patient who is relatively hypovolemic and receives a vasodilator or whose sympathetic tone is reduced by anesthesia. Hypotension is particularly common in patients with poor LV function. Conversely, in patients with good myocardial function, hypertension may occur during induction because of preinduction anxiety or sympathetic stimulation caused by laryngoscopy and endotracheal intubation.

The radial artery or an alternative site should be cannulated before induction of anesthesia to monitor arterial pressure on a beat-to-beat basis. If the radial artery is being harvested as a vascular conduit, the contralateral radial or brachial artery or a femoral artery can be cannulated. Basic monitors, including the ECG and pulse oximeter, should also be used during the induction of anesthesia. During any cardiac surgical procedure, central venous access is necessary to secure so that volume infusion, transfusion therapy, and vasoactive drug administration can be easily delivered directly to the central circulation. A central venous catheter or a PA catheter can be placed either before or after anesthesia is induced. Placement before anesthesia induction is ideal so that the CVPs can be monitored during the induction of anesthesia. However, the placement of these lines in the awake patient can take more time and create discomfort, thus causing unwanted hypertension and tachycardia. The risk-benefit analysis usually dictates that the central venous line be placed after anesthesia induction. The urinary bladder catheter, nasogastric tube, TEE probe, and any additional temperature monitors (e.g., a nasopharyngeal probe) are positioned after induction of anesthesia.

When choosing anesthetic drugs and doses during induction and maintenance, one should consider any pharmacodynamic properties that could affect arterial blood pressure, heart rate, or CO, as well as the desirability of "early" extubation of the trachea (i.e., within a few hours after the operation is completed). Anesthesia is most commonly induced with an opioid and a sedative-hypnotic (etomidate, thiopental, propofol, or midazolam). All anesthetics decrease arterial blood pressure by decreasing sympathetic tone, decreasing systemic vascular resistance (SVR), inducing bradycardia, or directly depressing myocardial function. The only exception is ketamine, which has sympathomimetic effects; however, in patients with catecholamine depletion, ketamine's sympathomimetic effects may not counterbalance its direct negative inotropic effects. Because of their pharmacologic complexities, all anesthetic agents should be administered judiciously in patients who are critically ill or who have poor LV function.

Muscle relaxants are usually given early in the sequence of anesthetic induction, particularly if relatively large doses of opioids are administered, to minimize chest wall rigidity (see also Chapter 27). With the routine use of fast-track anesthesia techniques, including a trend toward earlier extubation, volatile anesthetics are often chosen as the primary maintenance anesthetic. The predominant effect of isoflurane, desflurane, and sevoflurane is dose-dependent vasodilation with resultant decreases in SVR and arterial blood pressure. These volatile anesthetics may have an advantage in inducing preconditioning, which is particularly important in patients undergoing either CABG with CPB or OPCAB, in which myocardial ischemic insults are likely. The volatile anesthetic agents have several cardioprotective effects, including triggering the preconditioning cascade and mitigating reperfusion injury.[146] However, nitrous oxide probably should be avoided because it can increase gaseous bubble size and adversely affect pulmonary vascular resistance (PVR).

The Pre-Cardiopulmonary Bypass Period

After anesthesia is induced, several important details must be remembered, especially positioning (see also Chapter 34). Methods of positioning the arms vary according to institutional practice, but one must avoid causing brachial plexus injury by hyperextending the arms, ulnar nerve injury by improperly padding the olecranon, radial nerve injury by compressing the upper part of the arm against the sternal retractor support posts, or finger injury by entrapping the finger against the metal edge of the surgical table. Proper positioning also ensures that arterial catheters previously placed in the radial, ulnar, or brachial arteries are not "dampened." The head should be padded and occasionally repositioned during the procedure to prevent occipital alopecia, which can occur several days postoperatively. The eyes should be taped, possibly lubricated, and definitely free from pressure. Pressure-related injury to any soft tissue will potentially be exacerbated by hypothermia and decreased perfusion during CPB. All monitors and tubing should be checked after final positioning to ensure that none are kinked, entrapped, tangled, or inaccessible. Additionally, antibiotics must be administered (with documentation) within 1 hour of incision (vancomycin within 2 hours). Arterial blood gases and blood chemistry (electrolytes, glucose, and calcium), as well as baseline ACT, should be measured shortly after anesthesia is induced. If a continuous mixed venous PA catheter has been inserted, mixed venous hemoglobin oxygen saturation should be measured to calibrate the device.

During the prebypass period, the anesthesiologist's main goal is to maintain the hemodynamic and metabolic stability of the patient while making preparations for CPB. The degree of surgical stimulation varies markedly during this period. Positioning the patient, inserting additional monitors, preparing the skin, and harvesting the saphenous vein or veins cause only minimal sympathetic stimulation. Therefore, hypovolemic patients and those with poor ventricular function may be susceptible to hypotension during these periods. In contrast, chest incision, sternal splitting, and harvesting of the IMA involve more intense surgical stimulation. These events may cause hypertension, tachycardia, and dysrhythmias, even in previously hypotensive patients. However, just before CPB is initiated, during the cannulation of the great vessels, surgical stimulation is again minimal, and manipulation of the heart and great vessels may transiently decrease venous return and cause a precipitous decline in blood pressure. The anesthesiologist must be ready to treat all hemodynamic aberrations with the vasopressor, inotropic, vasodilator, antiarrhythmic, and anticholinergic drugs mentioned earlier.

In preparation for CPB, anticoagulation must be achieved. Heparin is still the standard drug used and is administered through a central venous catheter at an initial dose of 300 to 400 units/kg. The onset of anticoagulation is almost immediate, but generally, the drug is allowed to circulate for 3 to 5 minutes before its effect is measured. The ACT must increase to at least 300 seconds before CPB is initiated, although most institutions use at least 400 seconds as their standard. Additional heparin is administered, if necessary, to increase the ACT to the desired level. Subsequently, it is common to administer an antifibrinolytic drug (EACA or TA) in an attempt to minimize bleeding and the need for transfusion during cardiac surgery.

After heparinization, the next major step in the prebypass phase is vascular cannulation. One or more large veins or the right atrium is cannulated so that all systemic venous blood is diverted to the pump oxygenator. Additionally, a large artery, usually the ascending aorta, is cannulated so that oxygenated blood is delivered back to the arterial circulation. Heparin is always administered before cannulation. Usually, arterial cannulation is established before venous cannulation to allow rapid intravascular volume or blood resuscitation if necessary. Complications of aortic cannulation include arterial dissection, hemorrhage and resultant hypotension, inadvertent cannulation of the aortic arch vessels, and embolic phenomena caused by dislodged atherosclerotic plaque or by air introduced into or entrained around the aortic cannula. Complications of venous cannulation include hypotension from blood loss, dysrhythmias, and surgical mechanical compression of the heart or great vessels. When arterial cannulation is successful and the cannula has been inspected to ensure that no air is present, volume can be administered in 100-mL increments to treat bleeding and hypovolemia. If necessary, dysrhythmias are treated by cardioversion, medications, or rapid initiation of CPB.

Patients undergoing redo cardiac surgery (i.e., those who have previously had a median sternotomy) warrant special concern about the possibility of sudden, massive hemorrhage. At least 2 units of blood should be immediately available for all redo cases. Frequently, the surgeon will elect to use an oscillating saw in these patients, but mediastinal structures adherent to the underside of the sternum may nevertheless be injured. If the right atrium, right ventricle, great vessels, or an existing coronary graft is cut, the surgeon may elect to initiate CPB on an emergency basis. Therefore, the anesthesiologist should have a systemic dose of heparin prepared. As soon as the patient is heparinized, the femoral or aortic arterial cannula is inserted, and the cardiotomy suckers can be used to create venous return (so-called sucker bypass).

Onset of Cardiopulmonary Bypass

Preparing for the onset of CPB brings about a new set of challenges for a cardiac anesthesiologist. As a preparation for CPB, the surgeon would start by placing purse string sutures in the ascending aorta for the eventual placement of aortic cannula. It is imperative that at this point the anesthesiologist keeps the patient's blood pressure in a range that would not jeopardize the integrity of the aorta while the cannula is placed. A systolic blood pressure of 90 to 110 mm Hg is traditionally accepted for this stage of the procedure. Around this time heparin will also be administered. Usually 300 units/kg patient weight is administered for a target ACT of 450 to 500 seconds, to safely start the CPB. After the safe placement of aortic cannula, remaining cannulas will be placed by the surgeon, followed by start of the CPB.

During the abovementioned process, a cardiac anesthesiologist monitors the patient's hemodynamics and rhythm for any undesired changes.

With the onset of CPB, to guard against malposition of the aortic or venous cannula, the perfusionist checks the aortic inflow line pressure and for signs of inadequate venous return while the anesthesiologist checks for persistently low arterial pressure, unilateral blanching of the face, or any swelling in the neck veins, face, or conjunctiva. Once full bypass is established and aortic ejection by the heart has ceased, ventilation and inhaled drugs can be discontinued. If a PA catheter is present, it is pulled back 3 to 5 cm to minimize the risk of pulmonary perforation as the pulmonary arteries collapse. Prebypass urine output is recorded and emptied so that urine output during CPB can be monitored separately. The TEE probe may be used to watch for LV distention with the onset of CPB, which may indicate aortic valve regurgitation or other hemodynamic problems. Once CPB is established, the probe is left in the unlocked (neutral) position until the cardiac chambers are de-aired and the patient is weaned from CPB.

To ensure adequate anesthetic depth, supplemental intravenous sedative-hypnotics are administered, or a volatile agent is administered through a vaporizer connected to the oxygenator gas inlet of the CPB circuit. Administration of muscle relaxant is continued to prevent spontaneous ventilation, movement, or shivering during hypothermia and rewarming.

WEANING FROM CARDIOPULMONARY BYPASS

After the completion of surgery on CPB, the patient is prepared for coming off of the CPB and the resumption of patient's own physiology.

As part of a cardiac anesthesiologist's responsibilities it is of paramount importance that a plan is made beforehand for this part of cardiac surgery. The plan should take into account the nature of surgery, the length of bypass run, length of the aortic cross clamp and patient's presurgical cardiac status and comorbidities.

In preparation of weaning the patient off of the CPB several issues need to be addressed before a successful weaning process is started. Issues that need to be addressed include temperature, electrolytes (specifically potassium), rhythm, systemic blood pressure, contractility, and any air in the left ventricle (LV).

After addressing the abovementioned issues, the perfusionist gradually allows more and more blood to be pumped by the heart instead of the bypass machine. During this time the cardiac anesthesiologist ensures that any inotropic and/or volume requirements of the patient are met to successfully bring the CPB run to its conclusion.

The "CVP" Mnemonic

Fortunately, for most patients, separation from CPB is a relatively uneventful process. A review by Licker and colleagues emphasized that the key to successful weaning from bypass is clear communication among members of the operating room team.[147] In a study conducted at the Mayo Clinic in Rochester, Minnesota,[148] a strong correlation was noted between the frequency of technical errors and poor communication or coordination among the surgeon, anesthesiologist, and perfusionist.

Regarding clinical issues, several criteria should be met in all cardiac surgical cases before weaning from CPB is attempted. Morris and colleagues suggest a mnemonic, "CVP," to help the clinician remember the main tasks necessary for the successful termination of CPB (Table 54.4).[149] Each letter of CVP represents several tasks or important points to remember that begin with that letter.

The first "C" stands for cold, which refers to the patient's temperature at the time of weaning from CPB, which should be 36°C to 37°C. Neither the temperature of the venous blood returning to the CPB circuit nor the nasopharyngeal temperature should ever exceed 37°C because hyperthermia may increase the risk of postoperative neurologic complications (see the section on "Temperature").

The second "C" stands for conduction, which refers to cardiac rate and rhythm. A heart rate of 80 to 100 beats/min is usually desirable. Bradycardia is treated with epicardial pacing wires and/or with β-adrenergic drugs that have chronotropic and dromotropic, as well as inotropic, properties. Tachycardia (i.e., heart rate >120 beats/min) is also undesirable. Sinus tachycardia may result from anemia, hypovolemia, “light” anesthesia, or the administration of chronotropic drugs; treatment is tailored to the presumed cause. Rhythm is also an important factor in optimizing CO. Third-degree AV block requires pacing, ideally AV pacing. Sinus rhythm is preferable, particularly in patients with poor LV compliance, who are especially dependent on an “atrial kick” to achieve adequate filling. If supraventricular tachycardia is present, direct synchronized cardioversion is often warranted. In addition, pharmacologic therapy with amiodarone, esmolol, verapamil, or adenosine may be used in the initial treatment of or to prevent the recurrence of supraventricular tachycardia.

The third “C” stands for CO or contractility. Contractility may be estimated from TEE or PA catheter data, if available.

The fourth “C” refers to cells (i.e., red blood cells [RBCs]). The patient’s hemoglobin concentration should be 7 to 8 g/dL, or slightly higher, before weaning from CPB. If the hemoglobin concentration is less than 6.5 g/dL when rewarming commences, the perfusionist and anesthesiologist can consider hemoconcentration or transfusion of a unit of packed RBCs (PRBCs).

The fifth “C” refers to calcium, which should be immediately available for possible administration to treat hypocalcemia and hyperkalemia. Ionized calcium levels should be measured after rewarming to help direct therapy. Although calcium is not administered routinely, if ionized calcium levels are in the low-normal range, SVR can be beneficially increased by calcium administration.

The sixth “C” stands for coagulation. After protamine is administered, ACT is measured. In patients at risk for coagulation abnormalities, prothrombin time, PTT, and platelet count should also be measured a few minutes later. If POC coagulation monitoring such as the viscoelastic tests are available, these should be measured at this time. Examples of patients at risk for coagulation abnormalities include the following: those with long CPB times; those with extreme hypothermia, elective circulatory arrest, or both, during CPB; and those with chronic renal failure. Platelet function tests may be useful in patients taking platelet inhibitors (e.g., clopidogrel or aspirin). (For further discussion of patients having emergency surgery who are taking warfarin or who have been exposed to thrombolytic drugs, antiplatelet Gp IIb/IIIa agents, or direct thrombin inhibitors see the sections on the “hematologic system” and on bleeding and coagulopathy.)

The first “V” stands for ventilation of the lungs. As CPB is discontinued, the venous outflow line is gradually occluded, and PA blood flow is gradually restored. Pulmonary ventilation and oxygenation must be reestablished, thus allowing the lungs to become the site of gas exchange again. Ideally, the lungs are initially reinflated manually, with a few sustained inflations to a peak pressure of approximately 30 cm H_2O. If an IMA has been grafted to a coronary artery, the anesthesiologist must examine the surgical field during these inflations to ensure that the grafted artery is not overstretched, which could disrupt the distal anastomosis. Additionally, the compliance of the lungs is judged by these initial inflations, and bronchodilators can be administered if necessary. The surgeon should remove any fluid or blood from the pleural spaces and ensure that any pneumothorax is treated with a chest tube.

The second “V” refers to visualization of the heart, both directly in the surgical field (where the right-sided chambers are visible) and on the TEE, to estimate global and regional contractility. Furthermore, the degree of chamber filling (hypovolemic, euvolemic, or distended) can be estimated. In addition, one can do a final check for air within the cardiac chambers with TEE examination.

The third “V” stands for vaporizer, meaning that if volatile agents were used to ensure lack of awareness or to control blood pressure during CPB, the clinician usually reinstitutes a low dose immediately after weaning. However, because all the volatile agents decrease contractility and blood pressure, these effects can confuse the differential diagnosis of hypotension and myocardial dysfunction during weaning.

The final “V” refers to volume expanders. When all products from the pump have been exhausted and if blood transfusion is not indicated, crystalloid and albumin or hetastarch should be readily available to increase preload rapidly if necessary.

As for the letter “P” in the CVP mnemonic, Morris et al. explained that the first task “P” represents the need to be aware of predictors of adverse cardiovascular outcome.[149] For example, preoperative low EF and prolonged CPB often predict difficulty in weaning the patient from CPB and the need for inotropic support. In addition, emergency surgery in patients with acute coronary syndrome may lead to myocardial stunning. Furthermore, inadequate surgical repair (e.g., incomplete coronary revascularization) may result in ongoing ischemia.

The second “P” stands for pressure. Calibration and rezeroing are accomplished shortly before the patient begins being weaned from CPB. Any discrepancy between the distal (usually radial) arterial pressure and the central aortic pressure should be recognized. Occasionally, the surgeon may need to insert a temporary aortic root cannula or a longer-lasting femoral arterial cannula to monitor systemic blood pressure accurately during and after the termination of CPB.

The third “P” refers to pressors, meaning vasopressors and inotropic agents that should be immediately available. A vasodilator, such as nitroglycerin, nicardipine, or nitroprusside, also should be immediately available.

The fourth “P” represents pacer because an external pacemaker should be readily available for all patients. Pacing is often needed to treat bradycardia. In patients with heart block, ideally, an AV sequential pacemaker is used to maintain the atrial kick.

The fifth “P” stands for potassium because hypokalemia may contribute to dysrhythmias, and hyperkalemia may result in conduction abnormalities. In addition, the patient’s ionized calcium level is usually checked; most clinicians have a low threshold for administering additional calcium chloride. Furthermore, magnesium (2-4 g) is usually administered before CPB is terminated. Although magnesium’s efficacy in preventing postoperative atrial or ventricular dysrhythmias has not been clearly demonstrated, hypomagnesemia is common after CPB. The risk-to-benefit ratio for administering a 2- to 4-g dose is low.

TABLE 54.4 Elements of Morris, Romanoff, and Royster's "Central Venous Pressure" Mnemonic for Weaning Patients from Cardiopulmonary Bypass

C	V	P
Cold	Ventilation	Predictors
Conduction	Visualization	Pressure
Cardiac output	Vaporizer	Pressors
Cells	Volume expanders	Pacer
Calcium		Potassium
Coagulation		Protamine

From Morris BN, Romanoff ME, Royster RL. The postcardiopulmonary bypass period: weaning to ICU transport. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:230–260.

The final "P" refers to protamine. Many institutions require that protamine be uniquely packaged or kept in a nearby but separate area to ensure that the drug is not prematurely administered. (Administration during ongoing CPB is a disastrous error.) Nevertheless, it should take but a few moments to retrieve protamine when the surgeon, anesthesiologist, and perfusionist agree that it is time to reverse anticoagulation.

TERMINATION OF CARDIOPULMONARY BYPASS

After all the preparations described previously have been made and the patient's ventilation has been reestablished, the venous return to the pump is reduced by gradually clamping the venous line. The patient's intravascular volume is carefully increased by continued inflow through the aortic or other arterial cannula. Ventricular distention should be avoided because it increases wall tension and myocardial oxygen consumption. The pump flow into the aorta is lowered, in effect moving into a "partial bypass" phase, in which some of the venous blood still goes into the pump and some passes through the right ventricle and lungs to be ejected into the aorta by the LV. Some clinicians reduce the pump flow to half flow rather than gradually reducing venous return to the pump. Once loading conditions are optimal and contractility appears adequate, the aortic inflow line may be clamped to separate the patient from CPB.

If CPB has been successfully terminated but cardiac performance is not optimal, preload can be increased by infusing additional blood from the pump into the aortic cannula, usually in 100-mL increments in adult patients. Monitoring the left intraventricular volume in a qualitative fashion by TEE, observing the right ventricle directly, and monitoring the filling pressures give a good estimate of the adequacy of preload. At this point, the anesthesiologist and surgeon jointly determine whether myocardial filling and performance are adequate. This determination can best be accomplished by using TEE to observe the global and regional function of both ventricles. Supplemental information can be obtained by measuring CO, if possible. Afterload can also be optimized at this point. Usually, 95 to 125 mm Hg is a desirable systolic pressure in adult patients in the immediate postbypass period, whereas increased systolic blood pressure should be avoided to prevent excessive stress on suture lines in the heart and aorta. If the patient is hemodynamically unstable and additional time is needed to administer initial or additional inotropes or vasoconstrictors, CPB can be reinstituted by unclamping the venous outflow line and directing all flow to the oxygenator again (Fig. 54.11).

Once protamine is administered, the reinstitution of CPB becomes a more complicated process because the patient must first be reheparinized and antithrombin levels may be inadequate. Therefore, final checks of cardiac function, heart rate and rhythm, preload, afterload, and perfusion should be made jointly by the anesthesiologist and the surgeon. The venous cannula or cannulas are usually removed after the initial test dose of protamine is given. Many surgeons remove the aortic cannula only after at least half of the protamine dose has been administered. The rate and mode of protamine administration (incremental small boluses vs. continuous infusion) vary according to institutional and individual clinicians' practices, but a large dose of protamine should never be administered as a rapid bolus.

Table 54.5 shows the characteristics and treatment modalities of specific TEE-diagnosed difficulties that may be encountered during weaning and termination from CPB.[147]

CHEST CLOSURE

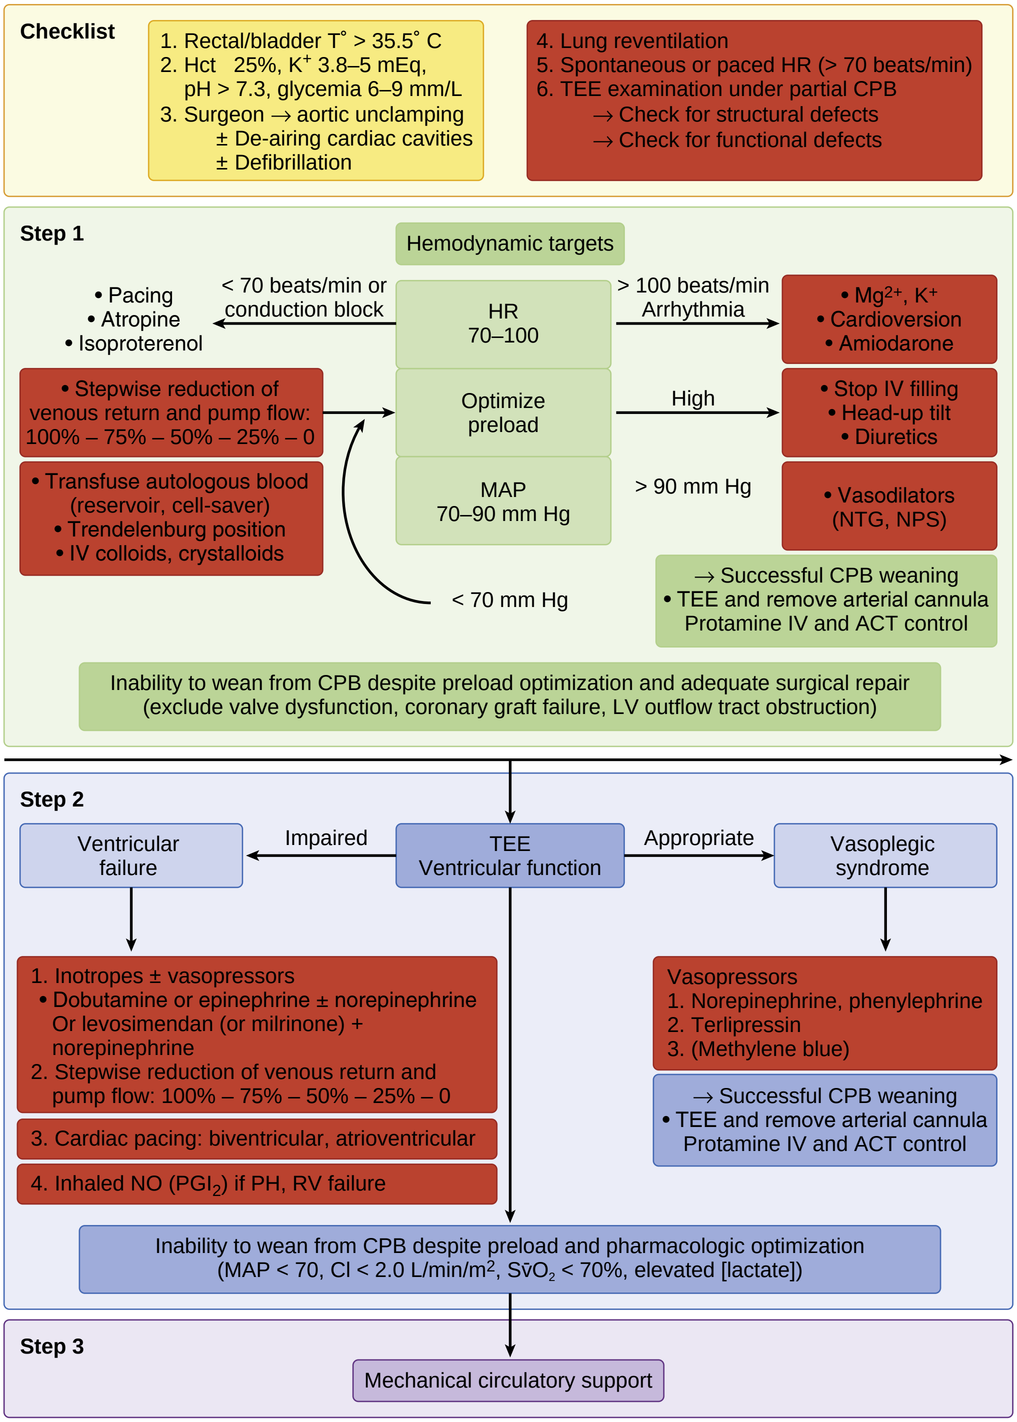
As the cardiac surgery proceeds toward its conclusion a critical step is still to come—chest closure. Chest closure is important because of the hemodynamic consequences that can result from it.

Usually the surgical team would announce the closure of the chest to the anesthesia team, but the anesthesiologists should remain vigilant of the timing of chest closure even if the surgeons do not announce it.

In the immediate post-CPB period patients are generally hypovolemic. Closure of the chest would exacerbate the consequence of hypovolemia (i.e., hypotension). To prepare for chest closure, anesthesiologists administer crystalloid, colloid, or blood depending on the patient's requirement. If chest closure causes severe hypotension surgeons should be requested to reopen the chest and wait until volume resuscitation has caught up (or at least the volume status is relatively easily manageable) to close the chest.

In addition to hypovolemia, chest closure is important in regard to causing ischemic changes by impinging on a venous or arterial graft that lies in a vulnerable position on or around the heart. In this situation ECG and/or hemodynamic changes will be observed which should prompt the anesthesiologist to inform the surgical team, who will reopen the chest and reposition the graft in a way that it is not affected by chest closure.

Other reasons for severe hypotension during chest closure in addition to hypovolemia and ischemia secondary to kinking of a coronary graft include impairment of RV contractility and venous return in patients with significant myocardial edema. TEE can be particularly useful in determining the cause of hypotension during chest closure because it can quickly reveal tamponade, hypovolemia, RV or LV global dysfunction, and severe new



Checklist
1. Rectal/bladder T° > 35.5° C
2. Hct 25%, K+ 3.8–5 mEq,
pH > 7.3, glycemia 6–9 mm/L

wall motion abnormalities. Reopening the chest may be necessary while treatment is instituted. Occasionally, the patient's sternum cannot be closed because of hemodynamic instability; in such cases, only skin closure is attempted, and plans are made to return to the operating room for sternal wiring after a period of myocardial recovery in the ICU.

TRANSPORT TO THE INTENSIVE CARE UNIT

Transportation of postcardiac surgical patients to the ICU is frequently dangerous and underestimated. Preparation for transportation of a postcardiac surgical patient should start with evaluation of the stability of the patient in the operating room. An ICU bed with a portable

hemodynamic monitor should be prepared and ready for these patients. Monitoring should not be completely interrupted even for a few moments. The ideal transport monitoring system has a "brick" that can be ejected from the operating room monitor and is compatible with the transport monitor. If such equipment is not available, sequential disconnection of monitors is advised so that an online monitor is always visible and the patient is never "unmonitored."

Staff should be educated about the importance of sequential transfer of monitors.

In the post-CPB period patients are frequently receiving infusions. A cardiac anesthesiologist should make sure that the pumps used for infusions in cardiac surgery are adequately functional. It is a good practice to unplug infusion pumps a few minutes before leaving the operating room to test the battery life for transport. Regardless of the proximity of the ICU to the operating room, disconnection of vasoactive infusions during transport could be devastating in certain critically ill patients.

As many patients are transported intubated, it is a good practice to carry a laryngoscope blade and an endotracheal tube. Even if the patient is extubated before leaving the operating room, airway management equipment and a means to ventilate the patient should still travel to the ICU with the patient. In addition, emergency medications should be brought during transport. It is recommended that the anesthesiologist carries at least one round of "code drugs" to assist in the event of cardiac arrest during transportation. A defibrillator should be on every patient's transportation bed.

Upon reaching the ICU, it is the responsibility of the cardiac anesthesiologist to ensure that a detailed report is given to the receiving physician or nurses.

On arrival in the ICU or cardiac recovery area, a transfer of the patient and the patient's information from one team to another, termed handoff or handover, occurs. Handoff failures have been identified as a significant source of medical errors, both between and within teams.[150-152] Implementing a handoff protocol reduces information omission and reduces errors. The process is intended to be strictly sequential: monitoring should be transferred before ventilator transfer, and all phase 1 items should be completed before information transfer.[153,154] Using formal, sequential handoff procedures does not increase the duration of the process.[155] The following sequence is suggested[155] (Wahr J, personal communication, November 17, 2012):

Phase 1: Equipment and Technology Handover

1. Monitoring transferred to ICU equipment
2. Ventilator function initiated
3. Infusions and fluids checked
4. Chest drains secured and on suction
5. Vital signs confirmed to be stable, ventilator functioning well, infusions running appropriately
6. Anesthesiologist, nurse, and surgeon confirm that they are ready for information transfer

Phase 2: Information Handover

1. Anesthesiologist presents
   a. Patient-specific information (age, weight, medical and surgical history, allergy status, baseline vital signs, pertinent laboratory results, diagnosis, current condition, and vital signs)
   b. Anesthetic information (intraoperative course and any complications, lines present, blood transfusion or fluid totals, paralytics or opioids, antibiotics, current infusions, vital sign parameters or limits, pain relief plan, laboratory values)
2. Surgeon presents: surgical course (diagnosis, operation performed, surgical findings, complications, blood loss, drains, antibiotic plan, deep vein thrombosis prophylaxis, medication plan, tests to be done, nutrition, key goals for the next 6 to 12 hours)

Phase 3: Questions and Discussion

In all cases, the anesthesiologist should remain with the patient until hemodynamic stability and overall stability are ensured.

THE POSTBYPASS PERIOD: COMMON PROBLEMS AFTER CARDIOPULMONARY BYPASS

Awareness

The potential for the patient's awareness must be assessed during and after CPB (see also Chapter 40). The incidence of this distressing complication is more frequent in cardiac operations than in other cases.[156,157] Although patients may sweat during the rewarming period, usually because of perfusion of the thermoregulatory site in the hypothalamus with warm blood, sweating may also result from awareness if anesthetic concentrations are low during the period when the brain becomes normothermic. Awareness may be more likely if considerable time has elapsed since any sedative-hypnotic or narcotic has been administered, if small doses of anesthetic drugs were administered during CPB, or if the patient is young. Consideration should be given to continuing to administer a volatile anesthetic agent once pulmonary ventilation is reestablished and to administering additional sedative-hypnotic doses, an opioid, or both. Some clinicians begin infusing an anesthetic agent such as propofol or dexmedetomidine shortly after weaning the patient from CPB and continue it during and after transport to the ICU or cardiac recovery area.

Published studies support the hypothesis that the use of depth-of-anesthesia monitors such as the BIS can decrease the incidence of intraoperative awareness in patients at high risk for this problem (see also Chapter 40).[156,157] However, falsely high BIS values during cardiac surgery have been attributed to interference from pump head rotation, pacemakers, and hypothermia itself.[158] Furthermore, because processing of the raw EEG and data smoothing to generate the BIS number occur over 15 to 30 seconds, the BIS number lags slightly behind clinical events.

Another important decision to be made is whether additional neuromuscular blocking drugs are needed during and after weaning from CPB. Use of a peripheral nerve stimulator may facilitate this decision (see also Chapter 43). Although movement of the patient may serve as an indication of the patient's awareness, such movement can be extremely dangerous if it results in dislodgment of the aortic or venous cannulas. Furthermore, shivering can occur because of the "afterdrop" in temperature after a period of hypothermic CPB. Because shivering can increase oxygen demand by 300% to 600%, it should be prevented by administering a neuromuscular blocking drug.

BOX 54.8 Risk Factors for Low Cardiac Output Syndrome After Cardiopulmonary Bypass

Preoperative left ventricular dysfunction
Valvular heart disease requiring repair or replacement
Long aortic cross-clamp time and total cardiopulmonary bypass time
Inadequate cardiac surgical repair
Myocardial ischemia and reperfusion
Residual effects of cardioplegia solution
Poor myocardial preservation
Reperfusion injury and inflammatory changes

From Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:1028.

Cardiovascular Decompensation (Low Cardiac Output Syndrome)

Although improvements in myocardial protection have occurred during recent decades, it is well documented that significant declines in LV function after CABG and other cardiac operations occur in the first 8 to 24 postoperative hours.[159] A combination of ischemia and reperfusion injury after cardiac surgery contributes to an energy deficit state in the myocardium that limits uptake of exogenous energy substrates from blood (Box 54.8). Prolonged aortic cross-clamp time, incomplete revascularization, or poor myocardial preservation adds additional risk. In particular, patients with preexisting LV dysfunction experience a delay in myocardial recovery after cardiac surgery and require measures to relieve the workload of the heart. Furthermore, preexisting diastolic dysfunction is associated with an increased risk of difficulty in weaning from CPB and ongoing need for vasoactive support during the postbypass period and in the ICU.[160]

Criteria used to define low CO syndrome (LCOS) include a cardiac index of less than 2.4 L/min/m^2, elevated lactate levels, and urine output of less than 0.5 mL/h for more than 1 hour.[161]

Postoperative management of patients at high risk for LCOS requires a physiologic approach. Optimizing preload and reducing afterload help maximize cardiac function.

TABLE 54.6 Relative Potency of Commonly Used Vasoactive Drugs

		CARDIAC			PERIPHERAL VASCULATURE	
	Dose	**Heart Rate**	**Contractility**	**Vasoconstriction**	**Vasodilation**	**Dopaminergic**
Norepinephrine	2-40 μg/min	+	++	++++	0	0
Dopamine	1-4 μg/kg/min	+	+	0	+	++++
	4-20 μg/kg/min	++	++, +++	++, +++	0	++
Epinephrine	1-20 μg/min	++++	++++	++++	+++	0
Phenylephrine	20-200 μg/min	0	0	+++	0	0
Vasopressin	0.01-0.03 units/min	0	0	++++	0	0
Dobutamine	2-20 μg/kg/min	++	+++, ++++	0	++	0
Milrinone	0.375-0.75 μg/kg/min	+	+++	0	++	0
Levosimendan	0.05-0.2 μg/kg/min	+	+++	0	++	0

From Hollenberg SM, Parrillo JE. Acute heart failure and shock. In: Crawford MH, DeMarco J, Paulus WJ, eds. *Cardiology*. 3rd ed. Philadelphia: Saunders; 2010:964.

Both tachycardia and bradycardia should be avoided, and postoperative arrhythmias should be treated. In addition, shivering should be prevented because it raises the heart rate by increasing oxygen demand. Postoperative deep sedation and muscle relaxation are often used to reduce myocardial workload by reducing the body's overall metabolic demand by 25% to 30%.

Pharmacologic support is often needed to improve contractility as the patient is weaned from CPB and, eventually, recovering in the ICU (Table 54.6).[161,162] Catecholamines (β-adrenergic agonists) and phosphodiesterase inhibitors are the main classes of pharmacologic agents used for this purpose. Catecholamines (e.g., epinephrine, norepinephrine, dopamine, dobutamine, dopexamine, isoproterenol) are often the first line of therapy. They exert positive inotropic action by stimulating the β_1 receptor, which leads to increased intracellular cyclic adenosine monophosphate (cAMP). The predominant hemodynamic effect of a specific catecholamine depends upon the degree to which the α, β_1, β_2, and dopaminergic receptors are stimulated. Phosphodiesterase inhibitors (e.g., milrinone, amrinone), sometimes termed inodilators, may be used either as first-line therapy or added to β-adrenergic therapy. Phosphodiesterase inhibitors augment β-adrenergic stimulation by inhibiting the breakdown of cAMP. When these drugs are added to catecholamine infusions, the result is an additive or possibly synergistic increase in inotropy. Phosphodiesterase inhibitors also induce systemic and pulmonary vasodilation. Hence, they are particularly useful in patients with pulmonary hypertension, RV failure, or aortic or mitral valve regurgitation.

Although not yet available in the United States, a newer class of drugs—the calcium sensitizers—exhibit potent inodilatory properties.[163,164] Levosimendan is the first such drug in this class, and has been studied extensively in other parts of the world. A randomized controlled trial of levosimendan in cardiac surgery in the U.S., (although it was found to be beneficial), did not meet its primary endpoint,[165] and thus the drug has not received approval by the U.S. FDA. Its mechanism of action is that it increases myocyte sensitivity to calcium by stabilization of the calcium binding to troponin C, thus enhancing actin-myosin cross-bridging and increasing contractility.[166] Therefore, inotropic performance is enhanced, whereas diastolic performance is preserved. Like phosphodiesterase inhibitors, levosimendan may augment inotropy without significantly increasing myocardial oxygen consumption.

RV failure may also be present in patients with LCOS, and it manifests as elevated PA and CVP pressures. Echocardiography can be diagnostic—findings include an enlarged and poorly contracting right ventricle, often with significant TR. The management of RV failure consists of ensuring adequate RV filling and maintaining adequate systemic pressures to prevent RV ischemia. Afterload reduction with agents effective in the pulmonary circulation is helpful. Milrinone may reduce PVR and improve CO. Nitric oxide and inhaled prostaglandins are selective for pulmonary vasodilation. Other measures to decrease PVR include hyperventilation (higher respiratory rate) to induce mild hypocapnia and aggressive treatment of hypoxemia and acidosis.

Right Heart Failure

Any situation where the right heart is not able to fulfill the requirements of circulation is labelled as right HF. With the development of new imaging modalities, it has become easy to accurately evaluate the right heart for management purposes.

Box 54.9 lists the key points of right HF which include the importance of identifying the problem in a timely manner with the help of new imaging modalities. A cardiac anesthesiologist can play a key role in this regard by using the three-dimensional TEE imaging. A number of parameters are used to evaluate right HF by the cardiac anesthesiologist using TEE: size of the right atrium and ventricle, RV systolic function, septal curvature, tricuspid regurgitation (TR), gradient across the RV outflow tract, and an estimation of the PA and RA pressures.[167]

Management of right HF starts by identifying the etiology of failure: ischemia, PE, outflow tract obstruction, air embolism, etc. Maintenance of sinus rhythm, reducing RV afterload, and inotropic support play an important role in supporting the right heart. Importance of maintaining adequate MAP should not be underestimated in these cases.

BOX 54.9 Key Points of Right Heart Failure

- Right ventricular (RV) function is associated with significant mortality
- New echocardiographic modalities using strain appear promising in predicting RV failure
- Monitoring the impact of RV function using near infrared spectroscopy and liver hemodynamics appear as useful intraoperative methods in adjusting therapeutic interventions and fluid management

From Haddad F, Elmi-Sarabi M, Fadel E, et al. Pearls and pitfalls in managing right heart failure in cardiac surgery. *Curr Opin Anesthesiol*. 2016;29:68–79.

Inhaled vasodilators are also used in right HF. In some institutions two inhaled agents are instituted with different mechanisms of action, especially in unexpected right HF cases.

Fluid management in these patients should be very judicious as they might already be congested.

Finally, mechanical support for the failing right heart is available and has seen significant advancement in the last few years. Depending on the situation of the patient, these devices can be either temporary or permanent in nature.[167]

Right Ventricular Dysfunction or Failure

RV dysfunction or failure may also occur after CPB, usually because of inadequate myocardial protection, inadequate revascularization with resultant RV ischemia or infarction, preexisting pulmonary hypertension, intracoronary or pulmonary air embolism, chronic mitral valve disease, or TR. Such RV failure may be evidenced by RV distention and hypokinesis on TEE, as well as by elevations in CVP and PA pressure (PAP).

Therapy for RV failure includes increasing preload and inotropic support; milrinone, dobutamine, and isoproterenol are the usual first-line drugs. Other pharmacologic drugs occasionally used to induce pulmonary vasodilation include nitroglycerin and nitroprusside. One potential problem with the use of intravenous inodilator and vasodilator agents is that their effects are not limited to the pulmonary circulation. SVR must be adequate to maintain RV perfusion pressure. Inhaled drugs such as nitric oxide, epoprostenol (Flolan), and inhaled iloprost are considered in refractory cases. Adjuncts to decrease PVR include hyperventilation (higher respiratory rate) to induce mild hypocapnia, and preventing hypoxemia and acidosis. Rarely, patients may require support with an RVAD.

Vasoplegia

Inappropriate vasodilation with a low SVR is another common cause of immediate post-CPB cardiovascular decompensation that may result in unacceptable hypotension. Predisposing factors include long-term administration of medications such as ACEIs or angiotensin receptor blockers (ARBs), prolonged duration of CPB, severe anemia with decreased viscosity, acid-base disturbances, and sepsis. Treatment with infusion of a vasoconstrictor drug such as phenylephrine, norepinephrine, vasopressin, or, rarely, methylene blue or B12 is usually successful.

TABLE 54.7 Postoperative Rate and Rhythm Disturbances

Disturbance	Usual Causes	Treatments
Sinus bradycardia	Preoperative or intraoperative β blockade	Atrial pacing β-Agonist Anticholinergic
Heart block (first, second, and third degree)	Ischemia Surgical trauma	Atrioventricular sequential pacing Catecholamines
Sinus tachycardia	Agitation or pain Hypovolemia Catecholamines	Sedation or analgesia Volume administration Change or stopping of drug
Atrial tachyarrhythmias	Catecholamines	Change or stopping of drug
	Chamber distention Electrolyte disorder (hypokalemia, hypomagnesemia)	Treatment of underlying cause (e.g., vasodilator, give K^+/Mg^{2+}) Possible need for synchronized cardioversion or pharmacotherapy
Ventricular tachycardia or fibrillation	Ischemia Catecholamines	Cardioversion Treatment of ischemia; possible need for pharmacotherapy Change or stopping of drug

K^+, Potassium; *Mg^{2+}*, magnesium.

Modified from Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis: Saunders; 2011:1030.

Dysrhythmias

Normal sinus rhythm is ideal because it provides an atrial contribution to ventricular filling and a normal synchronized contraction of the ventricle. However, either supraventricular or ventricular arrhythmias can occur in the immediate postbypass period.

Postoperative arrhythmias are frequently seen in postcardiac surgical procedures. Table 54.7[168] summarizes causes and treatments of common postoperative arrhythmias. Postoperative arrhythmias can be divided into atrial and ventricular arrhythmias.

Atrial Arrhythmias. Atrial fibrillation (AF) is the most common postoperative arrhythmia (27%-40%).[169,170] Patients are at highest risk for new-onset atrial fibrillation 2 to 3 days after cardiac surgery.[170] This arrhythmia can potentially prolong the patient's hospital stay and increase management costs by causing hemodynamic compromise or thromboembolic complications in the postoperative period.[171]

Many potential risk factors have been studied in efforts to predict the occurrence of postoperative atrial fibrillation. With advancing age, dilatation of the atrium interrupts cell-to-cell electrical coupling between atrial muscle fibers. Other preoperative risk factors for postoperative atrial fibrillation include a history of atrial fibrillation, chronic obstructive pulmonary disease, valve surgery, and postoperative withdrawal of a β-blocker or ACEI.[170]

Increased preoperative hemoglobin A1c,[172] physical activity of low intensity during 1 year prior to surgery,[173] Caucasian race,[174] obesity, and electrolyte disturbances (hypokalemia, hypomagnesemia) have also been shown to contribute towards increased risk of atrial fibrillation.

Perioperative factors include inadequate atrial protection during surgery, pericardial inflammation, autonomic imbalance during the postoperative period, change in atrial size with fluid shifts, electrolyte (potassium and magnesium) abnormalities, and excessive production of catecholamines.[175] Reduced risk has been associated with the postoperative administration of β-blockers, ACEIs, potassium supplementation, and nonsteroidal antiinflammatory drugs (NSAIDs).[170]

Treatment for atrial fibrillation includes both pharmacologic agents and electrical stimulation. Many studies have shown that β blockade significantly reduces the incidence of postoperative atrial fibrillation and that withdrawal of β-blockers increases risk.[176,177] Synchronized cardioversion is reserved for patients who show signs of hemodynamic instability during atrial fibrillation.[178] In the absence of hemodynamic instability, pharmacologic agents are used with the goal of preventing a rapid ventricular response. Drugs usually employed for this purpose include calcium channel blockers, β-blockers, magnesium, and amiodarone. Expert consultation should be obtained before treatment is initiated, especially in a stable patient.[177,178]

Ventricular Arrhythmias. Although ventricular arrhythmias occur after cardiac surgical procedures, sustained ventricular arrhythmias are relatively uncommon. Associated factors may include hemodynamic instability, electrolyte abnormalities, hypoxia, hypovolemia, ischemia or infarction, acute graft closure reperfusion, and the use of inotropic agents.[178]

Ventricular arrhythmias can range from simple premature ventricular complexes (PVCs) to VT. Simple PVCs do not pose a significant risk of life-threatening ventricular arrhythmia. Conversely, complex ventricular arrhythmias, including both frequent PVCs (>30/h) and nonsustained VT, may make patients prone to sudden death, especially in the long term. Sudden death is even more likely if ventricular function is also compromised. A study of 126 patients with postoperative complex ventricular ectopy found a mortality rate of 75%.[178] Patients with sustained ventricular arrhythmias have a poor prognosis in both the short and the long term.

Although hemodynamically unstable VT should be treated by synchronized cardioversion, patients with PVCs or short runs of nonsustained VT with hemodynamic stability do not need to be treated. Any reversible causes should be sought and corrected. Amiodarone is reserved for hemodynamically stable patients with VT or an uncertain rhythm. Ventricular fibrillation should be treated promptly with electrical defibrillation.[178] For long-term management of ventricular arrhythmias, in addition to antiarrhythmic agents, electrophysiologic studies or placement of an ICD should be considered.

Bradyarrhythmias. Bradyarrhythmias are not uncommon in the immediate postoperative period. In most cases, a temporary epicardial pacemaker is sufficient. In a small percentage of patients, a permanent pacemaker may be necessary, especially in patients with sinus node dysfunction or AV conduction disturbances after either CABG or valve repair.[178] Patients who need a permanent pacemaker may receive either a single-chamber or a dual-chamber pacemaker. Multiple factors dictate which particular device would most benefit an individual patient.[179]

BOX 54.10 Vasodilators Available for the Treatment of Perioperative Hypertension

Adenosine
α_1-Adrenergic antagonists
α_2-Adrenergic agonists
Angiotensin-converting enzyme inhibitors (enalaprilat)
Angiotensin II antagonists
Atrial natriuretic peptide (nesiritide)
β_2-Adrenergic agonists
Dihydropyridine-type calcium channel blockers*
Dopamine agonists
Hydralazine
Nitrovasodilators*
Phosphodiesterase enzyme inhibitors
Prostaglandins

*Intravenous vasoactive therapies in widespread use to treat perioperative hypertension.

From Levy JH. Management of systemic and pulmonary hypertension. *Tex Heart Inst J.* 2005;32:467–471.

Hypertension

Immediately after cardiac surgery, the patient remains prone to hemodynamic instability, including hypertension.[180] Causes of postoperative hypertension are often multifactorial and may include withdrawal from preoperative antihypertensive medications (e.g., β-blockers and centrally acting α_2-agonists), pain, hypoxemia, hypercarbia, and hypothermia. However, arterial vasoconstriction usually plays a central role in acute postoperative hypertension.[181] The hazards of untreated postoperative hypertension include increased myocardial work and oxygen consumption, MI, rhythm disturbances, cerebrovascular accidents, increased bleeding, and even suture line disruption. In the postoperative period, deepening sedation to control a hypertensive episode may not be the best or the only possible approach, particularly if early extubation (fast tracking) is desirable.[180,181]

Several pharmacologic agents are available for use as antihypertensive agents (Box 54.10).[181] The drugs most commonly used in clinical practice are the nitrovasodilators and the dihydropyridine-type calcium channel blockers. Because of its antiischemic effects and familiarity, nitroglycerin is often the first agent used to treat hypertension in patients who have undergone coronary revascularization. However, nitroglycerin is not always effective in such patients because it primarily causes venodilation rather than arterial dilation. In addition, patients tend to develop tolerance to nitroglycerin.[181]

Because arterial vasoconstriction plays an important role in the development of hypertension after cardiac surgery, the therapeutic agent chosen should usually be one that effectively reduces this vasoconstriction. Sodium nitroprusside, a nonspecific venous and arterial vasodilator, is a common choice. Though the risks of coronary steal with nitroprusside are theoretical,[181] patients with renal failure eliminate sodium nitroprusside more slowly than normal, which makes them vulnerable to the toxic effects of this drug's metabolites (cyanide and thiocyanate).

Fenoldopam is a short-acting dopamine agonist that causes arterial-specific vasodilation by stimulating D_1-receptors. Unlike sodium nitroprusside, fenoldopam increases renal blood flow to produce diuresis and natriuresis.[182] Nevertheless, the results of most clinical trials regarding the renal protective effects of fenoldopam are equivocal. In addition, severe hypertension may require higher doses of fenoldopam, which may be associated with undesirable increases in heart rate.

Dihydropyridine-type calcium channel blockers, such as nicardipine and clevidipine, selectively relax arterial resistance vessels without negative inotropic or dromotropic (conduction) effects and cause generalized vasodilation of the renal, cerebral, intestinal, and coronary vascular beds. Recently, due to manufacturing issues with nitroprusside, the price in the U.S. has risen to several thousands of dollars. For this reason, the author's institution now uses nicardipine as a first-line drug to treat hypertension.

It is important to ensure that the patient's intraarterial pressure is monitored adequately when any vasoactive agent is administered. Vasoconstriction or poor perfusion of the extremities may create a discrepancy between central aortic and peripheral arterial pressures.

While monitoring a patient's blood pressure it is important to take note of the position of the arterial line transducer. A transducer placed lower than the mid axillary line will give artifactually high blood pressure readings. In addition, a short radial arterial catheter may be "positional" if hand positioning is suboptimal, or "dampening" of the tracing may result from poor perfusion of the distal extremities. Occasionally, during the perioperative period, the cardiac anesthesiologist or surgeon must replace a distal peripheral arterial catheter (e.g., with a femoral arterial catheter) to ensure that the effects of vasoactive therapy are monitored accurately.

Renal Insufficiency

Perioperative renal failure that necessitates dialysis occurs in approximately 2% of patients.[183] Although the definition of renal insufficiency or failure varies among studies, three useful criteria are (1) a serum creatinine level more than 44 mmol/L (>0.5 mg/dL) higher than its preoperative value, (2) a serum creatinine level more than 50% greater than its preoperative value, and (3) a serum creatinine level more than 177 mmol/L (>2.0 mg/dL).[184] Another definition of acute renal insufficiency involves a classification scheme that uses the acronym RIFLE (Table 54.8).[185]

Preoperative risk factors that are commonly associated with postoperative renal dysfunction after cardiac operations include preexisting renal insufficiency, type 1 diabetes mellitus, age older than 65 years, major vascular surgery, arteriopathy, genetic predisposition, and recent exposure to nephrotoxic agents (e.g., radiocontrast dyes, bile pigments, aminoglycoside antibiotics, and NSAIDs).[183,184] Ejaz and colleagues showed that in addition to serum creatinine, serum uric acid is a significant predictor of AKI.[186]

TABLE 54.8 RIFLE* Classification Scheme for Acute Renal Failure

	GFR Criteria	Urine Output Criteria
Risk	Plasma creatinine increased 1.5× or GFR decrease >25%	<0.5 mL/kg/h × 6 h
Injury	Plasma creatinine increased 2× or GFR decrease >50%	<0.5 mL/kg/h × 12 h
Failure	Plasma creatinine increased 3×, acute plasma creatinine ≥350 μmol/L, or acute rise ≥44 μmol/L	<0.3 mL/kg/h × 24 h or anuria × 12 h
Loss	Persistent acute renal failure = complete loss of kidney function >4 weeks	
ESKD	End-stage kidney disease (>3 months)	

*Acronym for risk, injury, failure, loss, and end-stage kidney disease.
ESKD, End-stage kidney disease; *GFR,* glomerular filtration rate.
From Kuitunen A, Vento A, Suojaranta-Ylinen R, et al. Acute renal failure after cardiac surgery: evaluation of the RIFLE classification. *Ann Thorac Surg*. 2006;81:542–546.

In addition, several intraoperative factors may predispose a patient to renal dysfunction, including the need for emergency surgery, repeat cardiac surgery, valve surgery, and a CPB time exceeding 3 hours.[183,184] Other perioperative risk factors for renal dysfunction after cardiac surgery are hypovolemia, hypotension resulting from either hypovolemia or LCOS, and embolic phenomena. Furthermore, damage to nephrons in the medullary region of the kidney results in acute tubular necrosis; hypoxia is a common cause of damage to the nephrons in this region.[184]

Postoperative renal insufficiency in cardiac surgical patients is associated with longer ICU stay, longer overall hospital stay, and increased mortality.[183,184] Thus, this disorder should be prevented whenever possible. On the basis of studies conducted in patients with radiocontrast nephropathies, investigators theorized that hydration before radiocontrast media are administered may protect the kidneys.[184] Because the mechanism of renal injury after CPB appears similar to that triggered by the administration of radiocontrast dyes, it is thought that adequate hydration and maintaining normovolemia can help to prevent postoperative renal dysfunction in cardiac surgical patients.[184]

Several treatment modalities have been suggested to prevent or ameliorate postoperative renal dysfunction (Box 54.11).[184] Basic supportive therapy involves ensuring adequate CO, perfusion pressure, and intravascular volume. Discontinuing any nephrotoxic drug (NSAIDs, certain antibiotics) is usual. Diuretics are not helpful and may be harmful.[187] Unproven pharmacologic therapies include mannitol, calcium channel blockers, ACEIs, atrial natriuretic peptide, and *N*-acetylcysteine. Finally, if dialysis is needed, continuous dialysis may be better than intermittent dialysis.[188]

Central Nervous System Dysfunction

The risk of overt postoperative stroke has decreased over the last few decades.[30] However, an increased risk of neurologic complications remains in older patients,[189] as well as in patients undergoing combined CABG and valvular heart

BOX 54.11 Aims of and Treatment Modalities to Reduce or Prevent the Development of Postoperative Renal Dysfunction

1. Maintain adequate oxygen delivery—by ensuring adequate cardiac output, adequate oxygen-carrying capacity, and proper hemoglobin saturation.
2. Suppress renovascular constriction—by ensuring adequate volume preload and use of infusions of mannitol, calcium entry blockers, and angiotensin-converting enzyme inhibitors.
3. Promote renal vasodilation—by dopaminergic agents, prostaglandins, and atrial natriuretic peptide.
4. Maintain renal tubular flow—by loop diuretics and mannitol (which may act to prevent tubular obstruction, which can cause cellular swelling, ischemia, and death).
5. Decrease oxygen demand—by the use of loop diuretics and mild cooling.
6. Attenuate ischemic reperfusion injury—as a result of the release of oxygen free radicals and calcium ions.

Modified from Sear JW. Kidney dysfunction in the postoperative period. *Br J Anaesth*. 2005;95:20–32.

surgery or other complex cardiac surgical procedures.[190] Risk factors for overt neurologic complications are listed in Box 54.4. The impact of overt stroke is profound in terms of worse adjusted hospital outcomes, longer ICU and postoperative stays, and poorer downstream survival.[191]

A less well-defined entity, POCD or the newer terminology of PND, is far more common. Delirium is included in the definition of POCD, as are deficits of memory, concentration, and psychomotor speed. Early cognitive loss, once thought to be transient, may persist for 5 years after cardiac surgery in as many as 40% of patients.[192] Formerly, POCD was assumed to be caused by physiologic disturbances resulting from CPB. However, more recent studies have confirmed that POCD occurs with similar frequencies after on-pump cardiac surgery, off-pump cardiac surgery, coronary stenting, and noncardiac surgery.[193] Hence, current attention focuses on factors related to surgical stress, anesthetic agents, and patient-related predisposing factors, particularly the degree of preoperative cerebrovascular disease.[194,195] In fact, surgical procedures are likely to uncover a patient's susceptibility to cognitive loss that was already present and would eventually manifest even without surgery, usually as a result of the progression of cerebrovascular disease.[195] Although POCD is less devastating than stroke, its potential impact on quality of life and overall healthcare resource use is still profound.[196]

Neuroprotection Strategies. Numerous strategies have been tried to decrease the incidence and severity of neurologic injury in cardiac surgical patients. The most common nonpharmacologic approaches emphasize the reduction of macroemboli and microemboli. As described in earlier sections of this chapter, these strategies include avoiding aortic atheroma by using transesophageal or epiaortic echocardiography, optimizing the placement of the aortic cannula in the aorta, avoiding partial occlusion clamping of the aorta for proximal anastomoses by using a single cross-clamp, and, in selected patients, avoiding all cross-clamping of the aorta (the "no touch technique").[43,197,198] Other strategies to minimize particulate microemboli include the routine use of arterial filtration in the cardiopulmonary circuit and use of the cell saver before reinfusing blood suctioned into the cardiotomy, to remove particulate and lipid material.[199] Strategies to minimize air microemboli include carefully removing air after any procedure involving opening a cardiac chamber, and flooding the field with carbon dioxide to minimize embolism of air entrained into the heart from the surgical field.[200] Eliminating CPB by performing off-pump CABG surgery has been touted as a means to reduce emboli in selected patients, but this approach has not decreased POCD rates at 1 or 5 postoperative years.[201] Many of the late-occurring strokes are probably caused by atrial fibrillation. Early pharmacologic or electrical correction and adequate anticoagulation are mandatory (see the section on arrhythmias in the postoperative period).

Other nonpharmacologic approaches include perioperative temperature control, as well as blood gas management (α-stat or pH-stat) during hypothermic CPB. These considerations are discussed in the section on CPB.

Diabetes is recognized as a risk factor for stroke and delirium after cardiac operations.[202] Even in nondiabetic patients, hyperglycemia is extremely common during cardiac surgical procedures because of the stress response to surgery (as well as CPB), the resultant increases in circulating catecholamines and cortisol, and hypothermia-induced reductions in insulin effectiveness. Experimental evidence has revealed a relationship between hyperglycemia and worse outcome after different types of neurologic injury. However, attenuating the hyperglycemic response to cardiac surgery or CPB has proved difficult. Furthermore, concerns exist regarding inducing even a single episode of severe hypoglycemia with aggressive attempts to control glucose levels.[203] The aim of perioperative glucose control for most patients is a level between 140 and 180 mg/dL.[204]

The influence of intraoperative hemodynamics may influence neurologic and other outcomes. The prospective, randomized trial conducted by Gold and colleagues compared maintaining "normal" MAP (minimum of 50 mm Hg) with keeping the MAP elevated (target of 80-100 mm Hg).[205] These investigators found that the overall incidence of combined cardiac and neurologic complications was significantly lower in the high-MAP group. In another study,[206] investigators noted a higher frequency of hypoperfusion-type "watershed" strokes in patients who underwent cardiac surgical procedures with a MAP that was at least 10 mm Hg lower during CPB than before CPB. The current recommendation is to maintain higher targets for MAP (i.e., >50 mm Hg) in patients at high risk for neurologic injury. Because high-risk patients can be identified and a defined therapeutic window exists, pharmacologic protection would be very desirable. However, no definitively proven drug therapy currently exists for the prevention or treatment of neurologic injury after cardiac surgery.

Cerebral oximetry has been proposed to be of benefit in preventing neurologic injury in cardiac surgery, but the evidence is still lacking in this regard.

Postoperative Management of Central Nervous System Injury or Dysfunction. Postoperative stroke may be suggested by the patient's inability to follow commands or move all extremities shortly after the surgical procedure. Neurologic consultation should be obtained, including diagnostic imaging. Diffusion-weighted magnetic resonance imaging is the most sensitive and accurate imaging technique for postoperative cardiac surgical patients.[207] It detects more microembolic lesions than does conventional magnetic resonance imaging and is better able to find multiple watershed lesions.

Management of CNS injury or dysfunction after cardiac operations consists of general supportive measures. Hypotension should be avoided, and consideration should be given to using volume expansion, inotropic augmentation (pharmacologic or mechanical), or vasoactive medications (vasopressin or phenylephrine) to support blood pressure and brain perfusion. The brain oxygen supply-demand balance should be optimized through adequate oxygenation, sedation, and strict temperature control. Hyperthermia (fever) should be aggressively controlled. Both hyperglycemia and hypoglycemia should be avoided. Lytic therapy is of little use in cardiac surgery because it poses a risk of postoperative surgical bleeding.

POCD can manifest subtly, being evident only with psychometric testing, or, at the other extreme, it can manifest as postoperative delirium. *Delirium* is defined as an acute and overt change in cognition and attention, which may include alterations in consciousness and disorganized thinking.[208] In the cardiac surgical literature, the reported incidence of delirium depends greatly on the methods used for delirium assessment, varying from 3% (chart review only) to 8% (interviews with nurses); however, with rigorous daily mental status testing and the application of a validated diagnostic algorithm, the incidence may be as high as 53%.[209]

Risk factors include preexisting cognitive impairment, poor preoperative functional status, prior stroke or transient ischemic attack, depression, alcohol abuse, and abnormal preoperative laboratory values (glucose, sodium, potassium, and albumin).[208] Precipitating factors for delirium in the postoperative period include intraoperative and postoperative medications, particularly sedatives and analgesics. The postoperative environment in the ICU often results in sleep deprivation and overstimulation, contributing to the onset of delirium.[208] Complications of hospitalization and surgical procedures, including those that result in prolonged controlled ventilation and reduced mobility, also contribute to the development and severity of delirium.

Nonpharmacologic postoperative strategies to prevent delirium are listed in Table 54.9.[208] Medications, including those used to control pain and anxiety, are a common cause. Debate continues in the literature for a better drug to minimize the incidence of delirium between benzodiazepines and dexmedetomidine. For patients who develop agitation, the mainstay of treatment is a thorough review of medications, as well as removing other precipitating factors, such as low CO or perfusion state, metabolic disorders (e.g., hyperglycemia), fluid and electrolyte disturbances (hypoglycemia or hyperglycemia and uremia), constipation, urinary retention, and environmental noise. For patients in whom these nonpharmacologic interventions are not sufficient, an antipsychotic, usually haloperidol, is considered first-line therapy for agitation associated with delirium.

TABLE 54.9 Prevention of Delirium after Surgical Procedures

Module	Postoperative Interventions
Cognitive stimulation	Orientation (clock, calendar, orientation board) Avoidance of cognitively active medications
Improvement in sensory input	Glasses Hearing aids and amplifiers
Mobilization	Early mobilization and rehabilitation
Avoidance of psychoactive medication	Elimination of unnecessary medications Pain management protocol
Fluid and nutrition	Fluid management Electrolyte monitoring and repletion Adequate nutrition protocol
Avoidance of hospital complications	Bowel protocol Early removal of urinary catheters Adequate central nervous system oxygen delivery, including supplemental oxygen and transfusion for very low hematocrit Postoperative complication monitoring protocol

Modified from Rudolph JL, Marcantonio ER. Postoperative delirium: acute change with long-term implications. *Anesth Analg*. 2011;112:1202–1211.

Delirium may accelerate cognitive decline in patients with Alzheimer disease or cause a type of posttraumatic stress disorder in younger patients.[208] The long-term mental health implications of delirium have not been fully studied but may include impairment of functional recovery.

Peripheral Nerve Injuries. Peripheral nerve injuries are not uncommon in cardiac surgical patients and are often self-limited. These are the result of positioning of the upper extremities with inadequate padding of the ulnar nerve. In addition, the brachial plexus is also prone to injury from excessive stretch by the sternal retractor. Usual presenting symptoms are numbness, weakness, pain, decreased reflexes, and diminished coordination.

Phrenic nerve, recurrent laryngeal nerve, and sympathetic chain injuries have also been reported. Saphenous nerve injury during saphenous vein harvesting is also known to have been reported.

Respiratory Insufficiency

Respiratory failure is a very common complication of cardiac surgery. Pulmonary complications that arise immediately after CPB vary from mild to severe and include atelectasis, bronchospasm, hemothorax, pneumothorax, endobronchial intubation, mucus plugs or blood clots in the endotracheal tube, pulmonary edema, and pulmonary dysfunction that varies from a mild increase in the alveolar-arterial oxygen gradient to a form of adult respiratory distress syndrome (ARDS) known as postperfusion lung syndrome.[210] Atelectasis is a common cause of decreased arterial oxygenation in the postbypass period because during CPB either the lungs are not ventilated or very small tidal volumes are used. During controlled ventilation, it is common to apply positive end-expiratory pressure after CPB and in the immediate postoperative period.

Hemothorax is caused by the accumulation in the pleural cavity of blood and clot, which should be surgically removed before chest closure. Pneumothorax may result from entry of the pleural cavity during dissection of the IMA or from excessive positive-pressure ventilation of the lungs. Pneumothorax may not manifest until after chest closure; it is treated by inserting a chest tube. Endobronchial intubation may occur when the patient's head is partially hidden from the anesthesiologist's view. The expansion of both lungs should be confirmed during initial full ventilation before weaning from CPB, when the chest is open, so that a good view of both lungs may be obtained. If any blood or mucus is present in the endotracheal tube, it should be suctioned during and after weaning from CPB.

More severe postoperative respiratory insufficiency that causes difficulty in ventilator weaning may reflect intrinsic pulmonary problems such as CPB-related acute lung injury, transfusion-related acute lung injury, or cardiogenic pulmonary edema. Patients with marginal cardiac function may require diuresis, afterload reduction, or inotropy in order to assist with weaning from mechanical ventilation.

Preoperative efforts to minimize pulmonary complications after cardiac surgery include optimizing pulmonary function for patients undergoing elective surgical procedures.

In previous decades, critical care management after cardiac surgery included overnight mechanical ventilation, which today would be considered "prolonged ventilation." It is clinically important to have a period of controlled ventilation to allow rewarming and emergence from anesthesia, optimize cardiac function, and ensure hemodynamic stability and the absence of bleeding. However, many patients are currently removed from mechanical ventilation within 3 to 6 hours of arriving in the postoperative care unit (fast tracking), if appropriate criteria have been met (see Box 54.11).[211]

In planning for fast tracking, it is important to limit the use of narcotics and muscle relaxants during the surgery to a minimum and that administration be timed appropriately.

A majority of patients undergoing cardiac surgery indeed are extubated within a few hours of reaching the ICU. Multiple risk factors are responsible for prolonged intubation in patients that do require prolonged ventilator support. These factors include emergency procedures, low preoperative LVEF, advanced age, preoperative renal compromise, prolonged aortic cross-clamp time, hyperglycemia, recent MI, current smoking, and FEV_1 of less than 70% predicted.[211,212]

Pulmonary-related reasons for the inability to wean from mechanical ventilation include noncardiogenic pulmonary edema, pneumonia, severe COPD, ARDS, and pulmonary embolism. Nonpulmonary complications such as persistent postoperative bleeding, neurologic complications (including stroke and delirium), renal insufficiency or failure, gastrointestinal complications, and sepsis also may result in a need for prolonged mechanical ventilation. In a large study of ventilator dependency (i.e., ventilation for >72 hours) after cardiac surgery, survival was 76% at 30 days, 49% at 1 year, and 33% at 5 years.[213]

Furthermore, strategies to avoid ventilator-associated pneumonia should be employed. These include formal infection control programs, handwashing, maintaining adequate endotracheal tube cuff pressure, avoiding gastric overdistention, semirecumbent positioning of the patient, scheduled drainage of condensate from ventilator circuits, daily sedation "vacation," adequate nutritional support, early removal of endotracheal and nasogastric tubes, and avoiding unnecessary reintubation.[210,211]

Pain management should be included in postoperative efforts to minimize pulmonary complications. Sternotomy pain may limit the patient's ability to cough and perform deep breathing exercises, and incisional leg pain resulting from saphenous vein harvesting may prevent early ambulation, thus increasing the risk of pulmonary complications. The reader is referred to the later section on pain after cardiac surgery for other options for improving postoperative pain control and thereby minimizing splinting and complications such as lobar collapse, pneumonia, and increased duration of hospitalization.

Metabolic Disturbances

Metabolic disturbances after CPB can be highly varied and include derangements in the levels of calcium, potassium, magnesium, abnormal glucose metabolism, and alterations in urine output and temperature control.

Electrolyte Imbalance. After CPB, levels of calcium, potassium, and magnesium are usually lower due to hemodilution. Hypocalcemia can occur after CPB, particularly in bleeding patients who are receiving multiple blood transfusions with large amounts of citrate. This phenomenon is exacerbated by hypothermia and low-output states. Hypocalcemia should be corrected because it may reduce cardiac contractility. Routine administration of calcium is not encouraged however,[214] due to the possibility of reperfusion injury and possible spasm of the IMA graft.[214,215] There is also a possibility of decreased ventricular wall compliance and an acute rise in SVR as a result of a bolus dose of calcium.[216] The most commonly used agent for replenishment of calcium is 10% calcium chloride, given in small doses while monitoring the patient's blood pressure.

Hypokalemia in the immediate postbypass period is seen secondary to either diuretic therapy, mannitol therapy, or to insulin therapy for control of glucose during surgery. If an insulin infusion is used during CPB to control glucose, it is recommended that careful and frequent monitoring of glucose and potassium take place. Generally, insulin needs are less toward the end of CPB and the infusion rate can be decreased during this time to avoid hypoglycemia and hypokalemia. Depending on the level of potassium, replenishment may be needed and should be performed, as the post-CPB myocardium is exquisitely sensitive to hypokalemia. Hypokalemia contributes to increased automaticity and may lead to atrial or ventricular arrhythmias. Therefore, hypokalemia should be corrected by the carefully monitored administration of potassium through an infusion pump at a rate of 10 to 20 mEq/h, with frequent measurement of potassium, as well as glucose and arterial blood gases.

Hyperkalemia is another possibility in the postbypass period. Common etiologies can be secondary to impaired renal function or cardioplegia administration during CPB. Occasionally, hyperkalemia is severe enough to interfere with conduction. Usual strategies to counter hyperkalemia (hyperventilation, insulin, bicarbonate, diuresis, calcium) are effective in restoring potassium to normal levels.

Magnesium levels may also be low in the post-CPB period. Usual etiologies include hemodilution with magnesium-free fluids or diuresis; the presentation may be new dysrhythmias, ventricular dysfunction, or ischemia. If hypomagnesemia is suspected, and a magnesium level cannot be obtained in a short period of time, it is recommended that magnesium be replaced in the dose of 1 to 2 grams over 15 minutes.[217] Many centers routinely administer 2 to 4 g of magnesium during weaning or after CPB in an attempt to minimize the incidence of ventricular and atrial arrhythmias.

Hyperglycemia. Hyperglycemia is extremely common after CPB (see the earlier section on the endocrine system). Poor perioperative glycemic control in patients undergoing CABG is associated with increased morbidity and mortality.[218] In patients with diabetes, maintaining serum glucose less than or equal to 180 mg/dL during CABG reduces morbidity and mortality, lowers the incidence of wound infections, reduces hospital length of stay, and enhances long-term survival. In nondiabetic patients undergoing CABG surgery, maintaining serum glucose at less than 180 mg/dL has also improved perioperative outcomes. Current recommendations from the STS are to maintain a blood glucose of less than 180 mg/dL[219,220] in the early postoperative period and at less than 150 mg/dL in patients who require more than 3 days of ICU care as a result of ventilator dependency, the need for inotropes, mechanical device support, antiarrhythmic drugs, or renal replacement therapy.[218] There has been considerable debate over how tight to control blood glucose in these patients. Poor control has been linked with adverse outcomes, yet tight control of glucose was shown to cause a significant rise in the incidence of stroke in cardiac surgical patients[219] and was more prone to cause hypoglycemia consequences.

Treatment strategies for the control of glucose vary from institution to institution. Often an insulin infusion is started during the surgery with close monitoring of the blood glucose. If an insulin infusion is used, it is important that it be reduced as CPB is terminated so as to avoid hypoglycemia that may occur after CPB is weaned. Intravenous insulin boluses can also be used in addition to or instead of an infusion. In addition, since insulin causes potassium to migrate from the extracellular to the intracellular space, potassium should be carefully monitored and hypokalemia avoided.

Urine Output. Urine output can vary in the intraoperative period. This could be secondary to multiple factors. Normal or high urine output can occur in patients because they have adequate renal blood flow or in patients with compromised renal blood flow but in whom diuretic therapy has been administered. In oliguric patients, the differential diagnosis includes hypovolemia, hypoperfusion, or ischemic renal injury. In order to monitor renal function, we monitor the urine output frequently and communicate any prolonged decrease in urine output to the perfusionist and the surgical team so that timely steps can be taken to improve. Preservation of renal function is critically important in the cardiac surgery patient since adverse renal outcomes are associated with increased morbidity in the postoperative period.

Hypothermia. Although cardiac surgical patients are weaned from CPB after an appropriate period of rewarming and when the patient's temperature is close to 37°C, a drop in temperature is observed in the post-CPB period, called "afterdrop."[221] Hypothermia can lead to myocardial dysfunction, coagulopathy, and delayed metabolism of medications.

In order to prevent hypothermia, measures can be taken to prevent the afterdrop commonly seen after the patient is successfully separated from CPB. Careful monitoring of temperature is employed and measures that can be employed include the use of warm fluids, a forced air warming blanket, and raising the room temperature.

Pain

Pain after cardiac surgery can have many sources, including the sternotomy incision, chest tubes, vascular cannulation sites, and leg incisions (see also Chapter 81).[222] Chest surgical procedures through thoracotomy are especially debilitating because of pain and consequent respiratory dysfunction.[223] Some of the deleterious effects of postoperative pain after cardiac surgery are caused by the stress response and resultant inflammation and enhanced sympathetic tone, which can increase the heart rate, PVR, myocardial work, and myocardial oxygen consumption, all leading to myocardial ischemia.

Pain after cardiac surgical procedures can also cause respiratory complications related to diaphragmatic dysfunction. Moreover, the patient's pain may cause voluntary reduction of muscular movement in the thorax and abdomen, a phenomenon often described as "splinting," which may interfere with the patient's ability to cough and clear secretions. However, at present, evidence to state definitively that any postoperative analgesic technique significantly affects morbidity or mortality after cardiac surgery is insufficient.[224]

Unrelieved pain does have psychological effects. Pain-related anxiety, depression, and sleep deprivation may contribute to delirium in patients in the intensive care setting. A primary benefit of effective pain control is patient satisfaction. So-called fast-track anesthesia, entailing earlier extubation, a relatively brief stay in the ICU, faster discharge from the hospital, and lower overall cost, has become a standard of care for the cardiac anesthesiologist. Effective pain control probably helps achieve these goals.

Opioids remain the gold standard for pain control after cardiac surgery, but these drugs have side effects that include nausea, vomiting, urinary retention, decreased gastric motility, pruritus, sedation, and respiratory depression. A meta-analysis showed small incremental benefits for morphine analgesia that was patient controlled compared with nurse controlled in the treatment of postoperative pain after cardiac surgery.[225]

Intrathecal and epidural local anesthetics and narcotics have increasingly been used to improve analgesia in patients undergoing cardiac surgical procedures. However, neither meta-analyses nor randomized trials of central neuraxial analgesia in cardiac surgical patients have shown that these techniques improve outcome.[226,227] Nevertheless, in some studies, thoracic epidural analgesia did significantly reduce pain and the risk for dysrhythmias, pulmonary complications, and time to tracheal extubation, and it reduced analog pain scores at rest and with activity. A major concern with the use of intrathecal, and particularly epidural, analgesia in cardiac surgery is the administration of anticoagulation during the operation and consequent fear of spinal cord damage from a possible epidural hematoma,[227] although the incidence is reported to be rare. Other techniques include the use of bilateral single-shot paravertebral blocks[228] or intercostal nerve blocks followed by a subcutaneous continuous infusion of local anesthetic agents.[229]

Because all analgesics have side effects, some authors have suggested that it is better to use combinations of drugs or techniques (i.e., multimodal analgesia; see also Chapter 72). Although a multimodal approach to pain control after cardiac surgery is advocated, use of cyclooxygenase-2-selective inhibitors and nonselective NSAIDs remains contraindicated after cardiac surgery because of risk of thromboembolic events.[230]

Bleeding and Coagulopathy

Although inadequate surgical hemostasis is a common reason for blood loss after CPB, coagulopathy resulting from excessive contact activation, platelet dysfunction, and fibrinolysis can occur and must be excluded. Historically, the most common causes of excessive bleeding in cardiac surgical patients have been related to platelet activation, platelet consumption, and hyperfibrinolysis induced by the extracorporeal circuit. Despite the use of high-dose heparin, thrombin generation remains ongoing during CPB. This results in microvascular coagulation and fibrinolysis and has deleterious effects on platelet function.[231] In the current era, viscoelastic testing can be employed to help differentiate the causes of post-CPB bleeding among themselves and to distinguish coagulopathy from surgical sources of bleeding.

Patients who are taking antithrombotic or anticoagulant medication before cardiac operations constitute yet another subset of patients at risk for post-CPB bleeding. When possible, information should be obtained preoperatively about the degree of platelet inhibition so that if a patient is bleeding after CPB, the degree to which anti-platelet drug therapy may be a factor can be ascertained.[232] Chen and Teruya found that preoperative testing of platelet function using one POC platelet function monitor can identify patients at highest risk for perioperative bleeding; other monitors of platelet function can be used similarly.[233]

An evidence-based approach to the diagnosis and treatment of residual post-CPB microvascular bleeding entails the timely detection and treatment of specific causes of coagulopathy.[234] Patients with postoperative bleeding benefit from POC testing incorporated into a transfusion algorithm that uses pharmacologic and transfusion therapies. Algorithms are designed to minimize unnecessary and indiscriminate blood product transfusion.[235-237]

Transfusion to treat coagulopathy or anemia is sometimes indicated, but it carries a cost in terms of healthcare resources and patients' outcomes. A study of more than 1900 cardiac surgical patients found that patients who received transfusions had a 70% increased risk of death and a doubling of their 5-year mortality rate, after adjustment for comorbidities, compared with patients who received no transfusions.[77] A multinational study showed that differences in transfusion practices among countries may account for differences in outcomes.[238] A study of 10,000 patients who underwent CABG from the Cleveland Clinic database confirmed the association of transfusion with early and late (i.e., 10-year) mortality; this study used a balancing score to account for confounding.[239] In addition, Marik and Corwin performed a meta-analysis of 45 trials that examined complications of transfusion therapy and found that mortality was increased in transfused patients (odds ratio, 1.7, 95% confidence interval, 1.4-1.9).[240.]

Guidelines and Recommendations. The STS and the SCA published a joint statement in 2007 and an update in 2011 regarding practice guidelines for transfusion and blood conservation in cardiac surgery.[77,241] They noted six factors that appear to be important predictors of blood product transfusion in cardiac surgery:

1. Advanced age
2. Low preoperative RBC volume (i.e., preoperative anemia or low body surface area)
3. Preoperative antiplatelet or antithrombotic medications
4. Complex or redo operation
5. Emergency operation
6. Noncardiac comorbidities

The Task Force gave specific recommendations on blood conservation that included the following five points[241]:

1. Consideration should be given to the use of drugs that either increase preoperative blood volume (e.g., erythropoietin) or decrease postoperative bleeding (e.g., antifibrinolytic drugs).
2. Techniques of conserving blood, including cell saver sequestration and retrograde priming of the pump, should be included in the operative plan.
3. To spare the patient's blood from the insult of CPB, normovolemic hemodilution or platelet-rich plasmapheresis can be considered.
4. Institutions should implement transfusion algorithms supported with POC testing.
5. A multimodal application of all of the previously mentioned guidelines is the best way to conserve blood.

These recommendations are parallel to and completely congruous with the tenets of patient blood management, which is a novel approach to blood transfusion that focuses on patient-centered therapies. The three pillars of patient blood management are as follows:

1. Preoperative optimization of RBC mass
2. Perioperative minimization of RBC loss
3. Perioperative optimal treatment of anemia

Definition of Bleeding and Transfusion Triggers. The decision to transfuse the cardiac surgical patient is one that should be made with great caution and careful consideration because allogeneic transfusion has several associated risks. The excessively bleeding patient who has a surgical source of bleeding should be carefully assessed, and often, allogeneic blood products are required to maintain hemoglobin and the integrity of hemostasis until the source of bleeding is found. Patients who have excessive microvascular bleeding from a coagulopathic cause should have careful testing of the hemostatic system, usually with POC monitoring, to assess which blood products or pharmacologic products are needed. The problem in defining a trigger for transfusion is the ambiguity of the definition of bleeding. Many sources state that excessive chest tube drainage can be defined as more than 250 mL of bleeding per hour for at least 2 consecutive hours, or 300 mL of bleeding in a single hour. In addition to defining the severity of bleeding, these criteria also often help clinicians determine whether to return the patient to the operating room for surgical exploration.

Knowing when to transfuse RBCs is equally challenging because the triggers for transfusion often rely on hemoglobin level, which is a poor surrogate for tissue oxygen delivery. It is well known that cardiac surgery and CPB are associated with anemia, which poses certain risks.[242] These risks include renal failure,[243] other end-organ morbidity, and even mortality,[244] all of which have been demonstrated observationally in well-designed multivariate analyses. However, the lowest tolerable hemoglobin level clearly differs among patient populations and remains ill-defined in the literature. Nevertheless, the STS/SCA guidelines for blood conservation provide a framework for transfusion triggers within which most patients are treated appropriately. These triggers include a hemoglobin level of at least 6 g/dL during CPB and 6 to 7 g/dL before and after CPB.[241] However, underlying comorbidities can and do raise the minimum safe hemoglobin or hematocrit level.

If only standard laboratory testing is available, monitoring the coagulopathic patient in the operating room is limited to monitoring hemoglobin concentration, prothrombin time or international normalized ratio, activated PTT, platelet count, and levels of fibrinogen and fibrin degradation products. These parameters are of limited utility in the post-CPB patient because they do not interrogate platelet function and because their turnaround time is too slow to allow timely initiation of therapy. For these reasons, without POC testing of hemostasis, transfusion therapy is often initiated empirically and indiscriminately.

The platelet count provides quantitative information about platelet concentrations but little, if any, qualitative information about platelet function. Even platelet counts lower than 50,000/μL do not correlate with postoperative bleeding. Laboratory measures of platelet function, including bleeding time, aggregometry, and cytometry, are not rapid (requiring > 1 hour to produce results) and therefore are impractical for obtaining timely information intraoperatively. When unacceptable microvascular bleeding occurs, no matter what the platelet count, CPB-induced platelet dysfunction is often assumed to be the culprit; however, platelet function can now be measured at the point of care.

POC monitors may be able to provide more timely information about the coagulation cascade than can laboratory measures and to assess the dynamic nature of platelet function sequentially. Such monitors are designed to test segments of the hemostatic system. The viscoelastic tests are dynamic measures of whole blood clot formation and can measure platelet integrity and the strength of the platelet-fibrinogen bond. These tests include thromboelastography (TEG; Haemonetics, Braintree, MA), Sonoclot (Sienco, Arvada, CO), and rotational thromboelastometry (ROTEM; Tem Innovations GmbH, Munich, Germany). The response of platelets to an agonist stimulus is another means of measuring platelet function. Platelet function can be measured at the point of care in this manner by the Platelet Function Analyzer-100 (PFA-100; Siemens Healthcare, Malvern, PA), Plateletworks (Helena Laboratories, Beaumont, TX), VerifyNow (Accriva Diagnostics, San Diego, CA), and the Multiplate analyzer (Roche Diagnostics, Rotkreuz, Switzerland).[244] POC monitors have also shown promise in stratifying bleeding risk for patients who come to the operating room after receiving antithrombotic drugs, such as clopidogrel, prasugrel, or Gp IIb/IIIa receptor inhibitors.[245-249] Finally, POC monitors provide data to support the implementation of institutional policies and practices directed at blood conservation and transfusion in cardiac surgical patients.[241]

POINT-OF-CARE ALGORITHMS. The STS/SCA blood conservation guidelines strongly encourage multimodal efforts to reduce transfusion rates and conserve blood products (see also Chapters 49 to 50). Studies that used transfusion algorithms paired with POC data to guide therapy have found these measures to be both efficacious and cost effective.[76,241] Examples of standard POC algorithms, one using the TEG and one using the ROTEM, are shown in Figs. 54.12 and 54.13, respectively. Algorithms can be constructed to incorporate any particular dynamic POC monitor or monitors.[250-256] Studies that have incorporated many different varieties of POC tests have generally shown a reduction in or even the

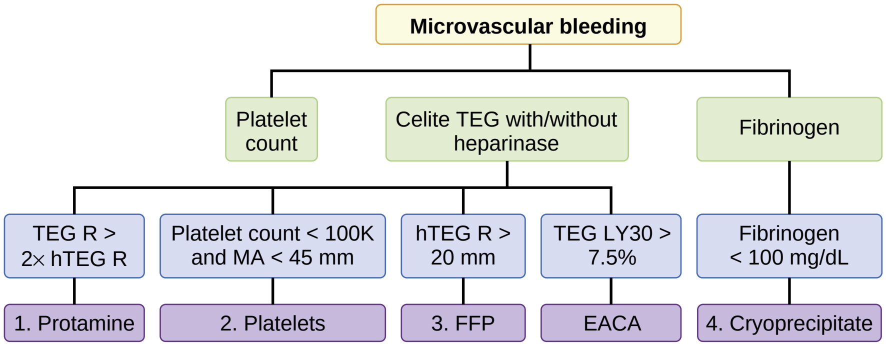

Fig. 54.12 Algorithm for transfusion requirements in the thromboelastography *(TEG)* group in a study. Once bleeding was diagnosed, patients received transfusions based on the results of tests in the algorithm. Based on the assumption that bleeding is often platelet related and on the finding that the platelet count and TEG results return promptly, therapy was given in the numbered order of priority. *EACA*, ε-Aminocaproic acid; *FFP*, fresh-frozen plasma; *hTEG*, heparinase-activated TEG; *LY30*, lysis index at 30 minutes; *MA*, maximum amplitude; *R*, reaction time. Point-of-care testing: a prospective, randomized clinical trial of efficacy in coagulopathic cardiac surgery patients. *Anesthesiology*. 2012;117:531-547.)

elimination of transfusions when POC is used.[254] As a general recommendation, the POC instrument or instruments used should be able to measure some aspect of platelet function. The viscoelastic test in the TEG measures both platelet function and the platelet response to ADP and arachidonic acid. Many TEG-guided and ROTEM-guided algorithms have been studied and shown to reduce blood product use effectively in cardiac surgery-related hemorrhage. A more recent approach to POC algorithm includes using ROTEM and an algorithm that includes early treatment with fibrinogen and PCCs (see Fig. 54.13).[257] This sort of approach to bleeding postpones the moment when allogeneic blood products are needed and thus has been successful in reducing allogeneic blood product usage. Preliminary work suggests that no increase in thrombotic events occurs with this "pharmacologic" approach to bleeding, but more large-scale studies need to be conducted before safety can be confirmed.

Pharmacologic Treatment. Pharmacologic drugs used for hemostasis in CPB are used both prophylactically to prevent hyperfibrinolysis and therapeutically to treat bleeding. Antifibrinolytic drugs are used before CPB to prevent the inevitable activation of fibrinolysis and coagulation that result from contact between blood and the extracorporeal circuit. The STS/SCA guidelines provide the strongest evidence-based support (class I) for the use of synthetic antifibrinolytic agents in blood conservation.

In structural terms, the synthetic antifibrinolytic agents are lysine analogues. They bind to plasminogen and plasmin, thus inhibiting their ability to bind to lysine residues on fibrin and thereby impeding fibrinolysis. The two synthetic antifibrinolytic agents that are used clinically are EACA (Amicar) and TA. They differ primarily in potency and elimination half-life: TA is 6 to 10 times more potent and has a longer half-life than EACA.[258]

Dose regimens for the synthetic antifibrinolytic agents are anything but standardized. Generally, the dose of EACA is a 50- to 150-mg/kg load followed by an infusion of 15 to 25 mg/kg/h; the dose of TA may be a 10- to 30-mg/kg load followed by an infusion of 1 to 15 mg/kg/h. However, many other dosing strategies are described in the literature.[259-264]

Because both EACA and TA are renally excreted, they should not be given to patients with upper urinary tract bleeding; the concentration of the drug in the renal collection system could cause thrombosis and obstructive nephropathy.[265]

Aprotinin as an antifibrinolytic agent was used as a routine part of perioperative care in cardiac surgical patients until 2006, when published reports suggested adverse outcomes that had not been found in previous randomized controlled studies.[119,266] After several observational studies confirmed these adverse outcomes and a single randomized controlled trial suggested an increase in mortality associated with aprotinin, the FDA and other global agencies suspended the marketing of aprotinin.[120]

Other pharmacologic drugs that may be used in cardiac surgical bleeding are mentioned in the STS/SCA Task Force guideline update.[76] Using desmopressin was classified as "not unreasonable" in patients with characteristics known to be responsive to desmopressin (von Willebrand factor or factor VIII deficiencies, cirrhosis, aspirin use, and uremic platelet dysfunction).[241] Desmopressin is administered in doses of 0.3 to 0.4 μg/kg, which are usually given slowly over 20 to 30 minutes to reduce the drug's propensity to cause hypotension. The use of recombinant factor VIIa (factor rVIIa) was reevaluated, but the published class IIb recommendation was unchanged in the update.[76] Factor VIIa use was classified as "not unreasonable" for treating intractable life-threatening hemorrhage that is unresponsive to traditional therapies.[241] A multicenter randomized trial in cardiac surgery found that patients treated with factor rVIIa had less bleeding than did control patients; however, a nonsignificant trend toward increased adverse events in the treated patients caused the study to be halted and the recommendations to proceed with caution when considering administration of this drug.[267] Prophylactic use of factor rVIIa is not recommended in cardiac surgery.

The PCCs have evolved into a more common treatment for coagulation factor deficiencies after CPB. 4-factor PCCs that were originally marketed either for hemophilia or for warfarin reversal have been used "off-label" in transfusion algorithms in bleeding cardiac surgical patients.[257]

In summary, interdisciplinary approaches to blood conservation are vital to the care of cardiac surgical patients. Perioperative and critical care personnel must use a series of combined approaches to reduce transfusions and the adverse effects of transfusion and anemia. Important to this approach is a sound algorithmic procedure that incorporates POC testing, pharmacology, and rational blood product use to improve outcomes.

Cardiopulmonary Bypass

CPB is a form of extracorporeal (*extra* = "outside of," *corporeal* = "the body") circulation (ECC) in which the patient's blood is rerouted outside the vascular system, and the function of the heart, the lungs, and, to a lesser extent, the kidneys is temporarily assumed by surrogate technology. The circuitry and equipment used to facilitate this substitution are topics of the next section of this chapter.

CIRCUITRY AND EQUIPMENT

The most common and most complicated ECC procedure is CPB. The goal of CPB is to provide a motionless and bloodless field for the surgeon by rerouting the patient's entire CO around both the heart and the lungs. Other ECC techniques include left heart bypass (LHB), cardiopulmonary support (CPS), and extracorporeal membrane oxygenation (ECMO).

The pumps, tubing, artificial organs, and monitoring systems used in CPB are diagrammed in Fig. 54.14. Simply stated, venous blood is intercepted as it returns to the right atrium and is diverted through the *venous line* of the CPB circuit to a *venous reservoir*. The *arterial pump* functions as an artificial heart by withdrawing blood from the reservoir and propelling it through a *heat exchanger*, an artificial lung (the *oxygenator*), and an *arterial line filter* before returning it through the *arterial line* to the patient's arterial system. Additional pumps and components are used to assist in the operation to manage shed blood (the *pump sucker*), decompress the heart *(vent)*, and deliver the *cardioplegia solution*.

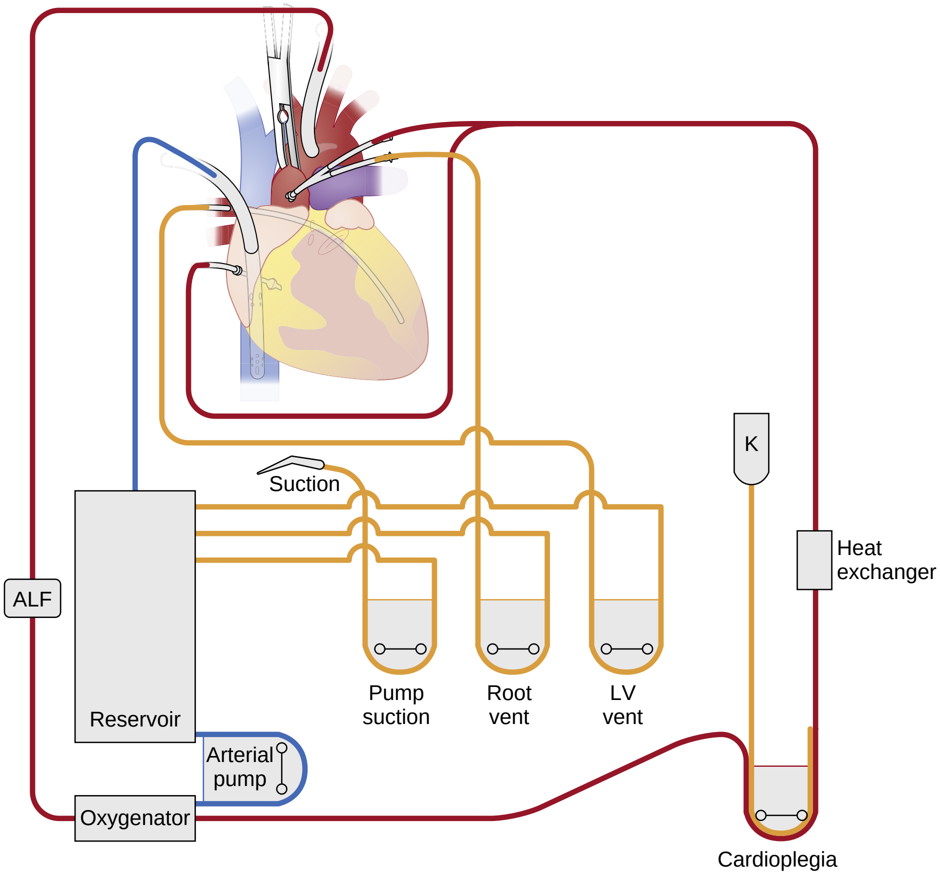

Fig. 54.14 A typical cardiopulmonary bypass circuit interfaced with a patient. *ALF,* Arterial line filter; *K,* potassium; *LV,* left ventricular.

Blood Tubing

The tubing used to connect the various components and conduct blood into and out of the patient's vascular system is medical-grade polyvinyl chloride. For decades, the blood-tubing interface was untreated polyvinyl chloride. However, the newer generation of polyvinyl chloride tubing has surface coatings and other modifications that significantly alter the bioreactivity of the surface. Collectively, these coatings have been shown to reduce plasma levels of markers of subclinical coagulation, attenuate the increase of cytokines and other inflammatory markers, and shorten intubation times.[268-270]

Venous Reservoirs

Blood reservoirs perform an important function in the conduct of CPB by facilitating the displacement of a large volume of blood out of the circulation at strategic times during the operation. Positioned between the venous line and the arterial pump, blood reservoirs may be collapsible plastic bags or clear plastic hard-shelled containers. Hard-shelled reservoirs include an integral filtration mechanism with a screen and depth filters through which blood must pass before leaving the outlet of the vessel. Almost universally, hard-shelled reservoirs have integrated positive- and negative-pressure release valves, which are necessary for the application of vacuum to the reservoir to augment venous drainage. If vacuum-assisted venous drainage is employed, the vacuum pressure in the reservoir should be maintained at the minimum necessary, and entrainment of air from the surgical field into the venous line should not be permitted. Reservoir pressures in excess of 60 mm Hg have been shown to increase microbubble counts measured in the circuit's arterial infusion line dramatically.[271]

Arterial Pumps

The pumping device used to replace the function of the heart generally uses one of two primary technologies: a roller pump or a centrifugal pump. Roller pumps are positive-displacement pumps that function by occluding a point in a piece of tubing and then rolling the occlusive point of contact along a length of the tubing. This process forces the fluid in the tubing to move forward in front of the occlusive point while simultaneously drawing in fluid behind the occlusive point. Centrifugal pumps, in contrast, are nonocclusive kinetic pumps that generate flow by magnetically coupling the high-speed revolution of a reusable motor to the plastic plates, fins, or channels inside a disposable cone. This process produces a constrained vortex that propels fluid through the opening on the side of the cone while drawing fluid into the point of the cone. Both pump technologies are traumatic to the formed elements in blood; however, centrifugal pumps are thought to be less traumatic than roller pumps.[272]

Each type of pump poses unique risks that must be appreciated. Roller pumps, by virtue of their occlusive nature, are capable of generating extremely high positive and negative pressure and are also able to pump massive quantities of air. Consequently, the national standard of care requires that these pumps be servoregulated to reduce their speed automatically when either high pressure or air is detected in the path of the blood. In contrast, centrifugal pumps, being nonocclusive, are unable to generate extremely high or low pressure. Additionally, if a large bolus of air is introduced into the disposable cone, the air will remain in the cone, thus displacing the blood, and the pump will be unable to generate forward flow. This feature prevents centrifugal pumps from pumping large volumes of air. However, the lack of a point of tubing occlusion inside the pump allows retrograde flow from the patient's high-pressure arterial system backward through the arterial line, filter, and oxygenator and ultimately into the low-pressure venous reservoir. This situation may occur whenever the pump's revolutions per minute are reduced below a critical threshold. A large-bore one-way valve or a computer-activated electronic clamp can be positioned in the arterial line to eliminate the possibility of retrograde arterial flow and inadvertent exsanguination of the patient.

Heat Exchanger

Heat exchangers are essential to CPB because they facilitate the management of the patient's blood temperature. Throughout the period of CPB, 20% to 35% of the patient's circulating blood volume is outside the body and is exposed to the ambient temperature of the operating suite, which can cause hypothermia. Therefore, in all CPB procedures, an inherent need exists to warm the blood before CPB is terminated. Additionally, for many surgical procedures, some amount of hypothermia, from mild (35°C) to profound (18°C), is desirable to reduce the patient's metabolic rate. In these cases, the heat exchangers may be used to reduce the temperature of the blood when CPB is initiated and then to warm the blood before CPB is terminated.

Oxygenator

The oxygenator substitutes for the patient's native lungs and performs the essential function of gas exchange. Several similarities exist between the native lung and the oxygenator: both have a gas space and a blood space, both are driven by passive diffusion gradients, and both use a membrane to separate the blood from the gas. In the oxygenator, the membrane is usually made from microporous polypropylene. This material is extruded into thin straws with an outer diameter of 200 to 400 μm, a wall thickness of 20 to 50 μm, and a total surface area of 2 to 4 m^2. Typically, oxygenators have a static priming volume of 135 to 340 mL and are capable of arterializing up to 7 L/min of typical venous blood.[273]

The native lung uses the conductive airways for both inspiration and expiration and depends on a certain tidal volume and respiratory rate to refresh the gas in the alveolar space regularly. The oxygenator, however, has separate gas inlet and outlet ports and can refresh the gas inside its gas space (the internal lumen of the straws) with a continuous flow or "sweep" of gas through the oxygenator. The blood space of an oxygenator is the space around the outside of the straws. Venous blood entering the oxygenator is directed across the outside of the fibers while gas is concurrently circulated through the inside of the fibers. Pressure gradients between the blood space and the gas space drive oxygen across the membrane and into the blood, whereas carbon dioxide is driven out of the blood and into the gas phase. Similarly, volatile anesthetic agents can be delivered to the patient through the oxygenator's sweep gas. Unlike the membrane in the native lung, however, the oxygenator's membrane is not a true membrane. The microscopic (0.5- to 1.0-μm) pores on the sides of the fibers are small enough to prevent plasma and the formed elements of blood from leaking through but are still large enough to allow gas to pass through. Therefore, care must be taken to ensure that the pressure in the gas space never exceeds the pressure in the blood space, or gaseous emboli will form in the blood. In appreciation of the risks inherent in using a pressurized gas space, most oxygenators are designed with multiple gas outlet ports. In any case, caution should be exercised to ensure that the outlet of the gas phase cannot become occluded.

Arterial Line Filter

In the United States, arterial line filters are used in more than 95% of CPB procedures in adults. These filters are placed in the arterial line as the last component through which blood passes before it returns to the patient. With pore sizes of 20 to 40 μm, arterial line filters increase the patient's safety by removing particulate and gaseous microemboli. To remove bubbles from the blood path effectively, arterial line filters must be continuously "purged" by allowing a small amount of blood to recirculate from the top of the filter back into the venous reservoir. Many ECCs are designed to capitalize on this continuous arterial shunt with the incorporation of a flow-through blood gas sensor that continually monitors the blood gas concentrations in the postoxygenator blood. These in-line blood gas measurements are generally reliable and can be used for the early identification of trends and precise management of oxygenator performance.

SEQUENCE OF EVENTS

Although the approach to surgical procedures that require CPB varies among institutions, all procedures loosely follow a predictable sequence of events. At any institution, CPB requires circuit selection and priming, anticoagulation, cannulation, initiation and maintenance of CPB, myocardial protection, and finally, weaning and termination from CPB.

Circuit Selection and Priming

When selecting the components for an extracorporeal circuit, the perfusionist first calculates the highest blood flow that may be necessary during the procedure. Typically, the highest blood flow is approximately 2.4 to 3.0 L/min/m^2 or 60 to 70 mL/kg/min. The calculated flow is then compared with the rated flow for the components of the ECC circuit. This flow rating represents the highest blood flow rate at which the component can perform its function within the acceptable range of hydraulic forces (pressure and shear stress) without causing an unacceptable amount of blood trauma.

The combination of components included in the ECC determines the prime volume of the circuit, or the volume of balanced electrolyte solution necessary to de-air the circuit

BOX 54.12 Resultant Hematocrit Formula

HCTr = Patient's preoperative red blood cell volume/Total volume of distribution at the start of CPB

$$\text{HCTr} = (\text{BVp} \times \text{HCT})/(\text{BVp} + \text{PVc})$$
$$\text{HCTr} = (\text{kg} \times 75 \times \text{HCT})/(\text{kg} \times 75) + \text{PVc}$$

where
HCTr = resultant hematocrit
BVp = patient's blood volume
kg = patient's weight in kg
PVc = prime volume of the extracorporeal circuit

CPB, Cardiopulmonary bypass.

completely. This prime volume is the main cause of the hemodilution associated with CPB. Therefore, the perfusionist must calculate the patient's resultant hematocrit (HCTr), which is the patient's predicted hematocrit after the patient's preoperative blood volume is mixed with the asanguineous prime volume of the ECC. The HCTr is computed by dividing the patient's calculated volume of RBCs into the calculated total volume of distribution represented by the addition of the ECC prime volume to the patient's blood volume (Box 54.12). An adult patient's intravascular volume of distribution will increase by 20% to 35% when CPB is initiated. This increased volume of distribution dilutes not only all the proteins and formed elements of the blood but also plasma levels of drugs. If this dilution is not anticipated, the patient's depth of anesthesia and circulating concentrations of many pharmacologic drugs may be reduced when CPB is initiated.

The solution used to prime the CPB circuit is generally a balanced electrolyte solution containing normal plasma concentrations of many of the standard blood ions. Various drugs may be added to the solution to attenuate the dilutional effect of CPB on those ions (e.g., albumin, heparin, bicarbonate) or to discourage edema formation or encourage diuresis of the prime fluid by the patient (e.g., mannitol).

Anticoagulation

With the circuit primed and the vessels exposed, standard procedure requires that the patient be fully anticoagulated before cannulation. Dosing of heparin and monitoring of the ACT are discussed earlier in this chapter. Many commercial devices are designed to monitor the ACT, and although the ACT is used as if it were a standardized test, the results produced by different instruments are far from standardized. These devices, when used on the same pool of heparinized blood, can produce ACT results that vary by as much as 40% (see Fig. 54.7).

The ACT test is not used to monitor heparin levels but to monitor the anticoagulant effects of heparin and other anticoagulants. Thus, elevated ACT measurements taken before, during, or after CPB may be influenced by variables other than heparin (e.g., hypothermia, hemodilution, coagulopathy, and anticoagulants).

Some studies suggest that subclinical coagulation may progress despite acceptable ACT times during CPB and that maintaining higher circulating heparin levels may reduce this process.[88,274] POC heparin level tests are commercially available and may be used to monitor circulating heparin levels in CPB-supported patients. Indeed, some centers monitor both the circulating level of heparin and its anticoagulant effects and administer heparin intermittently throughout the procedure to maintain a predetermined therapeutic heparin level, as well as a minimally acceptable ACT.

Heparin dosing may be based on the patient's weight (300-400 units/kg) or determined by a dose-response curve. Heparin dose-response curves are determined in vitro by measuring the ACT of the patient's blood at baseline (without heparin) and after a known concentration of heparin (2.5 units/mL) is added. By graphing the ACT in seconds against the blood concentration of heparin, one can extrapolate the blood concentration of heparin needed to achieve a target ACT acceptable for CPB. Most patients need circulating blood heparin concentrations between 1.5 and 3.0 units/mL to achieve an ACT of greater than 400 seconds. Commercial devices have been designed to automate this process and calculate the heparin dose using the in vitro dose-response curve, however these calculated doses do not simulate the in vivo response to heparin and often the calculations are flawed. Most centers have adopted a weight-based heparin dosing strategy for the initiation of CPB.[275] From the patient's height, weight, sex, and heparin dose-response test results, the machine calculates the appropriate patient-specific heparin dose to administer during CPB.

Cannulation

Every CPB procedure requires a high-flow cannula in a large vein and a cannula in a large artery for respectively withdrawing blood from and returning blood to the patient (Table 54.10). Most procedures include additional cannulas for administering cardioplegia solutions to the heart and removing (venting) blood and air from the chambers of the heart (Fig. 54.15). Different surgical procedures require different cannulation techniques, the most common of which are described here.

The target for venous cannulation is generally the right atrium. The right atrium is the central repository for all venous blood, and the RA appendage is conveniently accessible through a sternotomy. Although RA cannulation is optimal for most cardiac surgical cases, the cannula may not perform well when the heart is being retracted. Significant retraction of the heart is necessary to access some posterior coronary arteries for bypass or to access the mitral valve through a left atriotomy. Because of a need for surgical exposure or retraction involving the right atrium, the venous cannulation site for mitral valve or tricuspid valve procedures is moved out of the atrium and to the SVC and inferior vena cava (IVC). If a cannula is placed in each vena cava, venous blood can be intercepted just before it enters the right atrium so that the surgeon can have a bloodless field for operating and yet acceptable drainage is provided throughout the procedure. The right atrium may also be approached through the femoral vein. A femoral venous cannula extends the entire length of the IVC and rests with its openings in the right atrium.

An improperly sized or positioned venous cannula obstructs the flow of blood into the ECC circuit. This may elevate CVP and encourage extravasation of blood volume from the vascular compartment into the extracellular compartment (third spacing). Therefore, it is important to

TABLE 54.10 Common Approaches to Venous and Arterial Cannulation for Cardiopulmonary Bypass

Procedure	Venous	Arterial	Cardioplegia	Vent	Comments
CABG	2-stage approach in the RA	Ascending aorta	Root and/or CS	Aortic root	Patients with low EF or failure to wean from CPB may benefit from LV venting
AVR	2-stage approach in the RA	Ascending aorta	Root and/or CS, plus handheld selective once the root is open	LV and aortic root	None
MVR	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	None
Aortic root replacement, not including the arch	2-stage approach in the RA	Ascending aorta	Root and/or CS	LV and aortic root	The closer the repair is to the head vessels, the more difficult aortic cannulation becomes
Aortic arch	2-stage approach in the RA	Axillary or femoral artery	Root and/or CS	LV and aortic root	CS cardioplegia unlikely if the coronaries are unobstructed
Redo procedures	Femoral vein	Femoral artery	Root and/or CS	Aortic root and/or LV	Only in extreme cases (i.e., when the heart is tightly adhered to the back of the sternum, or any time that the heart is lacerated during sternotomy)
Other intracardiac procedures	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	Any procedure that requires opening the RA or excessive surgical retraction

AVR, Aortic valve repair or replacement; *CABG,* coronary artery bypass grafting; *CPB*, cardiopulmonary bypass; *CS,* coronary sinus; *EF*, ejection fraction; *LV,* left ventricle; *MVR,* mitral valve repair or replacement; *RA,* right atrium.

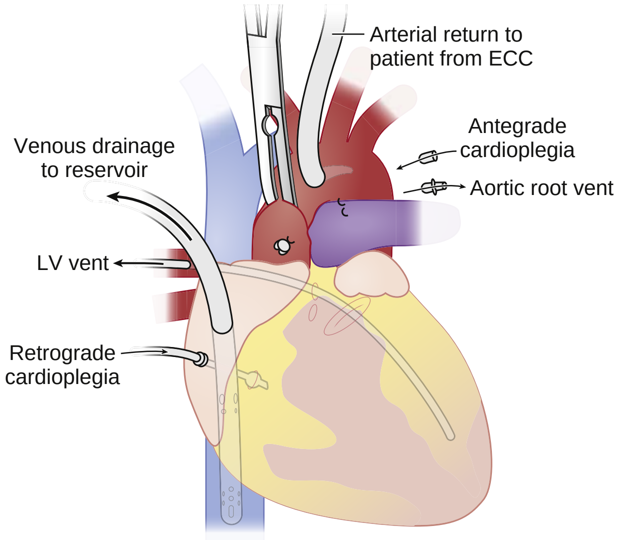

Fig. 54.15 A common cannulation approach for cardiopulmonary bypass (CPB) procedures. Two cannulas are necessary to provide CPB. A cannula in the right atrium provides venous drainage to the extracorporeal circuit *(ECC)*, and an arterial cannula placed in the ascending aorta allows arterial return to the patient from the ECC. Additional cannulas are necessary to protect the heart after cross-clamping. Cardioplegia can be administered in antegrade fashion through a special needle placed in the ascending aorta between the aortic valve and the aortic cross-clamp. Retrograde cardioplegia can be delivered directly into the coronary sinus through a special balloon-tipped cannula. Vent cannulas are used to decompress the heart while the aorta is clamped and to remove bubbles before cross-clamp removal. The aortic root vent is integrated into the antegrade cardioplegia needle, and the left ventricular *(LV)* vent cannula is inserted through the right superior pulmonary vein.

evaluate the performance of the venous cannula or cannulas when CPB is initiated. Properly placed venous cannulas allow complete decompression of the right side of the heart, as indicated by a CVP and PAP of zero and a nonpulsatile arterial blood pressure.

The ECC returns oxygenated blood to the patient through the arterial cannula. For CABG and valve procedures, the standard target for the arterial cannula is the portion of the ascending aorta below the aortic arch but 3 to 4 cm above the aortic valve. The alternative approaches of axillary or femoral artery cannulation are used in procedures that require the manipulation of much of the aortic root, arch, or both. Axillary artery cannulation is generally facilitated by the anastomosis of a tube graft to the side of the axillary artery to provide access for the arterial cannula without interrupting blood flow to the right arm. An added benefit of axillary cannulation for aortic arch procedures is that clamping the innominate artery allows antegrade cerebral perfusion to be performed during a period of circulatory arrest. Femoral arterial cannulation involves inserting the cannula through the femoral artery and into the abdominal aorta. Blood flow to the thorax is directed in retrograde fashion upward into the aorta. Ischemia of the cannulated limb is a risk commonly associated with femoral arterial cannulation, and dissection of the cannulated artery is a risk associated with the cannulation of any arterial site. Iatrogenic aortic dissection at the cannulation site occurs in approximately 200 procedures annually in the United States, with a resultant mortality of 48%.[276] Proper cannula placement and patency should be confirmed before CBP is initiated.

With venous and arterial cannulas in place, the heart and the lungs can be bypassed. However, additional cannulas are needed to facilitate aortic cross-clamping and cardioplegic arrest. For example, cardioplegia cannulas can be placed in the ascending aorta, and then the aorta can be occluded by placing a large vascular clamp (i.e., a cross-clamp) across it. Occluding the aorta between the arterial cannula and the antegrade cardioplegia cannula interrupts blood flow from the arterial line of the ECC to the coronary arteries, thereby initiating a period of global myocardial ischemia. Intermittent or continuous administration of cardioplegia through the antegrade and retrograde cardioplegia cannulas (see Fig. 54.15) serves to attenuate the ischemic insult (by a mechanism discussed later).

Bronchial pulmonary vascular connections deliver approximately 1% of the CO to the lungs, from where it is subsequently returned to the left side of the heart. In patients with chronic pulmonary disease, this recirculation may increase to more than 10% of CO. During the period when the aorta is cross-clamped, this blood volume will distend the left side of the heart and the pulmonary vasculature if the blood is not actively removed. Additionally, intracardiac procedures inherently introduce air into the left-sided chambers, and this air must be removed before the patient is weaned from CPB.

Vent cannulas facilitate decompression and de-airing of the heart. The heart is most commonly vented at the aortic root or directly from the LV. Aortic root vents use the same cannula that is used to deliver antegrade cardioplegia (see Fig. 54.15) and draw blood and air from the LV across the aortic valve and into the reservoir of the ECC circuit. Because the antegrade cardioplegia needle has a small gauge and is positioned above the aortic valve, root vents have a couple significant limitations: they cannot be used when antegrade cardioplegia is being administered, and they are ineffective in decompressing the LV when the cross-clamp has been removed. These limitations are not generally significant during an uncomplicated CABG procedure, but for CABG in patients with severely compromised ventricular function and for all intracardiac procedures, direct LV venting becomes essential. Typically, LV vents are introduced through the right superior pulmonary vein and are advanced through the left atrium, across the mitral valve, and into the LV (see Fig. 54.15). The 10- to 14-Fr cannula used for this purpose offers significantly better venting capacity than does the root vent. Flows in the range of several liters per minute can be drawn through these cannulas when necessary, and because these cannulas are inserted directly inside the LV, they are very effective in removing air bubbles that remain after an intracardiac procedure has been completed. Additionally, because the LV vent is separate from the cardioplegia cannula, it can be used to decompress the heart during antegrade cardioplegia administration, which may be necessary for patients with aortic insufficiency. Unfortunately, numerous case reports exist of injuries to patients that resulted from air being pumped into the heart through malfunctioning vent lines. The proper function of the vent pump should be confirmed at the field before the pump is connected to the patient.

Initiation and Maintenance of Cardiopulmonary Bypass

Once anticoagulation is confirmed and cannulation is performed, CPB may be initiated. Before initiating CPB, it is good practice to verify the patency of the arterial cannula. After the proper position of this cannula is confirmed, CPB may be initiated by removing the clamps on the venous line between the venous cannula and the reservoir. The patient's blood then passively drains into the ECC. Simultaneously, the arterial pump on the CPB machine begins to infuse the mixture of prime solution and autologous blood into the patient through the arterial cannula. Evaluating the performance of the venous and arterial cannulas is very important during the initial seconds of CPB. The pressure in the arterial line of the ECC should be maintained at less than 300 mm Hg to prevent excessive trauma to the formed elements of the blood. Venous cannula position is evaluated mainly by examining the patient's hemodynamics. Provided the venous cannula is adequately draining the venous return to the heart, right-sided heart pressure (CVP and PAP) should decrease to 0 mm Hg, and the arterial blood pressure should reach a normal mean pressure (50-90 mm Hg) while also becoming nonpulsatile.

The arterial trace usually becomes nonpulsatile as the heart is emptied and the pumping force is changed from the ventricle to the nonpulsatile heart and lung machine. However, patients with aortic insufficiency continue to have a pulsatile arterial trace despite complete venous drainage (CVP and PAP = 0 mm Hg) because of regurgitation of blood from the arterial cannula across the incompetent aortic valve and back into the LV. If right-sided heart pressure does not reduce to 0 mm Hg, the arterial trace remains pulsatile, and arterial pump flow cannot be increased to full flow; in that case, the position of the venous cannula must be reevaluated. Once full flow has been achieved, the function of the heart and lungs will have been completely transferred to the CPB machine; the anesthesiologist then can turn off the ventilator, and hypothermia of the patient can be initiated.

The initiation of CPB is often associated with a period of hypotension, which can be managed with the administration of an α-agonist (e.g., phenylephrine) into the venous reservoir of the ECC circuit (Fig. 54.16). Although it is common for cerebral oximetry values to reduce transiently at this point, acutely reduced cerebral oximetry values on CPB initiation may provide the first indication of poor SVC drainage or selective perfusion of a single aortic head vessel.[277-279] Markedly changed cerebral oximetry values warrant additional confirmation of cannula position and function. While CPB is maintained, the adequacy of perfusion is continuously evaluated by monitoring hemodynamic variables. Blood flow from the arterial pump can be manipulated across a range of 1.6 to 3.0 L/min/m^2 to deliver an arterial blood pressure of 50 to 90 mm Hg and maintain $S\bar{v}O_2$ greater than 65%. Any hypotension or hypertension that occurs despite adequate flow and $S\bar{v}O_2$ can be treated by adjusting the patient's SVR with vasoconstrictors or vasodilators.

Blood samples should be taken at least every 30 minutes. Arterial blood gas is drawn to assess the performance of the oxygenator and to monitor the patient for the development of acidosis. Base deficit values of −5.0 mmol/L or less can be corrected with sodium bicarbonate, but the underlying cause of the acid production should ultimately be addressed. Increased perfusion flow and blood pressure may be indicated. ACTs are drawn to assess continued adequacy of anticoagulation and values shorter than the institutional parameter acceptable for CPB (usually ≥400

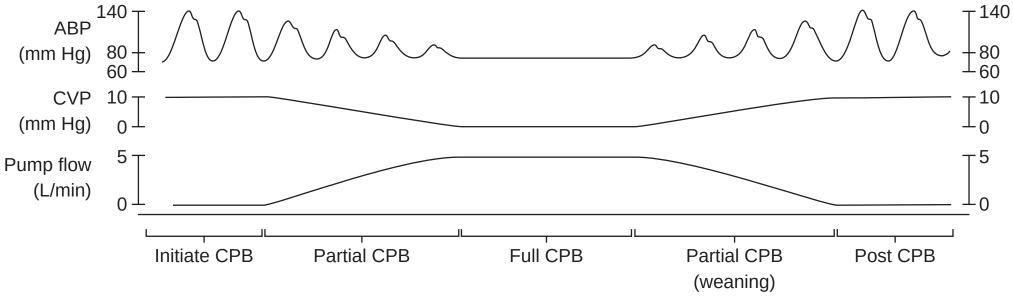

Fig. 54.16 Illustration of a patient's hemodynamics before cardiopulmonary bypass *(CPB)*, during the initiation of CPB, during full CPB, while weaning from CPB, and after CPB. *ABP,* Arterial blood pressure; *CVP,* central venous pressure.

seconds) should be treated with a heparin bolus administered into the ECC.

Urine output is also monitored during CPB as an indicator of perfusion flow and pressure. However, poor urine production during CPB has not been shown to predict postoperative renal insufficiency. Rather, age, preoperative renal function, the duration of CPB, and EF have been correlated with postoperative renal dysfunction.[280]

Myocardial Protection

To provide a motionless field for the surgeon, the heart is arrested in diastole by the administration of a potassium-enriched cardioplegia solution. Cessation of myocardial electromechanical activity is the single most important step in reducing the heart's metabolism. Potassium-induced arrest alone reduces the heart's myocardial oxygen consumption by 90%. It is common to augment this reduction with hypothermia by administering cold cardioplegia solution. The combined influence of potassium arrest and myocardial temperatures lower than 22°C reduces myocardial oxygen consumption by 97% and enables the tissue to withstand a complete interruption of blood flow for periods of 20 to 40 minutes. Once the surgical procedure is completed, myocardial arrest can be reversed by reperfusing the coronary arteries with warm normokalemic blood.

The ingredients of cardioplegia solutions vary considerably from institution to institution, save that potassium is always used as the arrest agent. Whereas some centers may use a very simple solution of potassium-enriched whole blood, others may choose a more complex solution with a variety of chemical additives. The trend in clinical practice has been not to use purely crystalloid cardioplegia solutions; instead, most centers now use some form of blood cardioplegia. The ratio of blood to crystalloid is generally 4:1 or 8:1. The crystalloid solution is often mixed with arterialized whole blood from the ECC circuit in an exact ratio by placing two different-sized tubes (the larger drawing from the arterial line of the ECC and the smaller drawing from the bag of cardioplegia solution) through a single roller pump and splicing the two tubes together downstream from the outlet of the pump. Generically, the chemicals added to the cardioplegia solutions are designed to make the solution slightly hypertonic to reduce edema, and these chemicals include a buffer to counter the heart's production of acidic metabolites and a substrate for energy or catalysts to assist the heart in the production of adenosine triphosphate. Typically, solutions with two different potassium concentrations are used during the procedure. For inducing cardioplegic arrest, a "high-K" solution with a potassium concentration of approximately 20 to 30 mEq is used. After isoelectric arrest is induced, the solution is changed to a "low-K" mixture with a potassium concentration of approximately 10 mEq.

These solutions can be administered in *antegrade* fashion into the coronary arteries via the aortic root, through a needle placed between the aortic cannula and the aortic valve, or in *retrograde* fashion into the coronary veins, via a balloon-tipped cannula placed in the coronary sinus. Antegrade cardioplegic delivery is the most physiologic approach. However, when the patient has pronounced CAD or aortic valve insufficiency, antegrade administration may not reach the coronary arteries uniformly and thus will not adequately deliver cardioplegia to the myocardium. In these instances, retrograde cardioplegia is used. Limitations of retrograde cardioplegia also exist however, and include the fact that the free wall of the right ventricle and the posterior onethird of the interventricular septum (the distribution territory of the right coronary artery [RCA]) are poorly perfused by retrograde delivery.[281] Additionally, the microvascular areas of the heart that are perfused by retrograde cardioplegia are less able to sustain normal myocardial energy metabolism.[282] Thus, the most complete technique for myocardial protection involves both antegrade and retrograde delivery. In fact, it is not uncommon for cardioplegia to be delivered simultaneously in both antegrade and retrograde fashion.

Cardioplegia is commonly administered intermittently in a volume-dosing regimen. After an initial arrest dose of approximately 1000 to 1500 mL of "high-K" solution is administered, perfusion of the heart is suspended for a period of 10 to 40 minutes while the surgeon operates on the heart. Then, periodically throughout the procedure, 200- to 500-mL doses of "low-K" solution are administered to deliver nutrients to the cells and maintain the potassium concentration. Intraoperative evaluation of the adequacy of myocardial protection is empirical and based on the quiescence of the ECG, the time since the last dose was administered, and the temperature of the heart. The filling state of the ventricular chambers should also be evaluated. If the vent lines are not keeping the heart empty, it will warm more quickly and the heart muscle will be under tension. This state increases myocardial oxygen consumption and compromises myocardial protection. To reinstitute the electromechanical activity of the heart, warm, normokalemic blood is infused into the coronary arteries. This may be done by administering a "hot shot" through the cardioplegia cannulas or by simply removing the cross-clamp.

Weaning and Termination of Cardiopulmonary Bypass

The process of weaning the patient from the heart and lung machine requires an increased level of communication and awareness among the anesthesiologist, perfusionist, and surgeon. Before weaning and termination, the patient should be rewarmed and the heart de-aired. Regular cardiac electrical activity should be confirmed and supported with a pacemaker if necessary. Ventilation of the lungs must be resumed and laboratory values confirmed and corrected if needed. By slowly reducing venous drainage to the ECC and transfusing volume from the reservoir to the patient, normal filling volume can be returned to the heart. As the CO is returned to normal, flow from the arterial pump of the heart and lung machine is decreased and eventually terminated. Immediately after the termination of CPB, the patient is often hemodynamically supported by volume replacement with the blood remaining in the ECC, frequently supplemented with vasopressors or inotropic agents (see the earlier section on weaning from CPB).

When the patient is hemodynamically stable, protamine can be administered to reverse the anticoagulatory effect of heparin. The administration of protamine to the patient is a sentinel event that must be communicated clearly by the anesthesiologist to the perfusionist and surgeon. In the event of inadvertent return of blood containing protamine to the ECC through the pump sucker, the blood remaining in the circuit may clot and render the circuit unusable for urgently reinstituting CPB. Therefore, all cannulas should be removed before the action of heparin is fully reversed, and the blood remaining in the ECC should be salvaged by centrifugation or hemofiltration for return to the patient by the anesthesiologist.

Protamine inactivates heparin by irreversibly binding with the strongly acidic heparin molecule to form a stable salt with no anticoagulant effects. POC tests are available for several ACT machines to calculate a patient-specific protamine dose.[283] If an automatically generated protamine dose-response curve is not available, many institutions calculate the protamine dose needed from the total dose of heparin delivered to the patient. This calculation usually results in the administration of 1 to 1.3 mg of protamine for every 100 units of heparin given. Protamine should be administered slowly over a period of 5 to 10 minutes to reduce the risk of hypotension. After protamine administration, ACTs should return to baseline. An increased ACT may indicate residual heparin or may be the result of a coagulation deficiency that necessitates additional laboratory tests, such as coagulation panel tests, heparin assays, platelet function analysis, thromboelastography, or any combination of these investigations.

OTHER ISSUES

Temperature

Deliberate hypothermia is a reliable method of neuroprotection and is often used during routine CPB. Deep hypothermia unquestionably confers cerebral protection when the circulation must be arrested during cardiac surgery. Even mild hypothermia (as little as 1°C-2°C) minimizes the severity of cerebral ischemia in animal models. Various suggested mechanisms for the neuroprotective effects of hypothermia have been tested in animal models (Table 54.11).[284] Hypothermia may attenuate the effects of cerebral ischemia by creating a favorable balance between oxygen supply and demand, and by decreasing the cerebral metabolic rate of oxygen. Hypothermia not only reduces the metabolic rate but also delays the release of excitatory amino acids, neurotransmitters that play an important role in the process of neuronal death. Additionally, hypothermia reduces the permeability of brain arterioles and prevents blood-brain barrier dysfunction. Hypothermia may also interfere with the inflammatory response by suppressing the adhesion of polymorphonuclear leukocytes in the damaged region.

TABLE 54.11 Protective Effects of Hypothermia and Deleterious Effects of Hyperthermia During Cerebral Ischemia

Hypothermia	Hyperthermia
Favorable balance between oxygen supply and demand	Imbalance between oxygen supply and demand
↓ Excitotoxic neurotransmitter release	↑ Excitotoxic neurotransmitter release
↓ Blood-brain barrier permeability	↑ Blood-brain barrier permeability
↓ Inflammatory response	↑ Inflammatory response
	↑ Free radical production
	↑ Intracellular acidosis
	Destabilized cytoskeleton

From Hindler K, Nussmeier NA. Central nervous system risk assessment. In: Newman M, Fleisher L, Fink M, eds. *Perioperative Medicine: Managing for Outcome*. Philadelphia: Saunders; 2008:69–88.

However, after performing a meta-analysis, Rees and colleagues concluded that no definitive evidence for a neuroprotective effect of hypothermia during routine CPB exists,[285] although the studies examined in that analysis had some important limitations. For example, the timing of hypothermia may have limited its protective value. Hypothermia is always initiated after aortic cannulation and the onset of bypass, but macroembolization to the brain is unlikely during this period because the heart is excluded from the circulation by the aortic cross-clamp. Instead, the periods of highest risk for microembolization and macroembolization are during and shortly after aortic manipulation, cross-clamping, and unclamping because aortic cannulation and cross-clamping are performed near the start of CPB, when the brain is not yet cold. Similarly, the aortic cross-clamp is removed near the end of CPB, usually after the patient has been rewarmed.

In contrast, hyperthermia is known to be deleterious. Elevation of body temperature by as little as 2°C decreases cerebral tolerance to ischemia. Hyperthermia delays neuronal metabolic recovery and increases excitotoxic neurotransmitter release, oxygen free radical production, intracellular acidosis, and blood-brain barrier permeability, with subsequent multifocal breakdown at sites in the thalamus, hippocampus, and striatum (see Table 54.11). Hyperthermia also affects protein kinase activity and destabilizes the cytoskeleton. Clinically, fever and hyperthermia worsen the prognosis of hospitalized patients with stroke.[286]

TABLE 54.12 Summary of Blood Gas Management Strategies

Strategy	Goal	Implementation	Total CO_2 Content	Theoretic Benefits
α-stat	Achieve electrochemical neutrality by maintaining a constant OH^-/H^+ ratio	Use normal *temperature-uncorrected* blood gas values	Constant	Preserves enzyme function and cerebral autoregulation
pH-stat	Maintain constant pH	Use normal *temperature-corrected* blood gas values	Increases	Produces more homogeneous brain cooling; decreases brain O_2 consumption
Combination	Maintain constant pH during cooling, then restore electrochemical neutrality before circulatory arrest	During the cooling phase, use *temperature-corrected* values, then switch to *temperature-uncorrected* values before interrupting flow; use *temperature-corrected* values during the rewarming period	Initially increases during cooling, then returns to baseline	Produces homogeneous brain cooling, then restores neutrality; improves $CMRO_2$

$CMRO_2$, Cerebral metabolic rate of oxygen; *CO_2,* carbon dioxide; *O_2,* oxygen; *OH^-/H^+*, ratio of hydroxyl ion to hydrogen ion.

In the 1990s, some centers began using normothermic cardioplegia to improve cardiac outcomes while avoiding deliberate hypothermia. This practice of "warm heart surgery" was debated because of concern that the neuroprotective effects of hypothermia would be lost. Subsequent studies produced inconsistent results with respect to the incidence of stroke and postoperative neurocognitive decline. Such differences in neurologic outcome may have resulted from variations in the temperature management strategies used in different "warm heart surgery" studies; these variations ranged from allowing a downward "drift" that resulted in actual mild hypothermia to active rewarming that may have led to inadvertent cerebral hyperthermia.[287]

In patients undergoing CPB, cerebral hyperthermia during the rewarming period may aggravate any cerebral injury that has occurred. Aggressive rewarming was once commonly practiced to prevent the "afterdrop" in temperature that usually occurs after CPB is discontinued, but this practice can cause cerebral hyperthermia at the exact moment when cerebral embolization is most likely. Therefore, rewarming should be gradual and should start early enough to achieve stability of the desired temperature before CPB is terminated.[288]

The surgeon should also be aware of the limitations of any temperature-monitoring site used during CPB. Brain parenchymal temperature cannot be measured directly during cardiac surgery; rather, it must be estimated from tympanic, nasopharyngeal, esophageal, rectal, bladder, skin surface, pulmonary arterial, or jugular venous bulb temperature. However, concordance between cerebral temperature and temperatures measured at most of these sites is poor.[289,290] Jugular bulb temperature is generally considered to be the gold standard because the proximity of the jugular bulb to the carotid artery origins and the aortic cannula makes jugular bulb temperature more similar to brain temperature than are temperatures measured at other commonly used sites (class I, Level C).[290,291] Temperatures measured at the nasopharyngeal, esophageal, bladder, rectal, or skin surface sites underestimate jugular bulb temperature during rewarming.[289,290] Because monitoring jugular bulb temperature is not usually feasible, monitoring the temperature of the blood in the arterial line that exits the oxygenator is considered the closest surrogate for brain temperature.[290,292] Temperature measured in the PA or the nasopharynx (class IIa, Level C) are also reasonable sites to monitor during weaning from CPB.

Hyperthermia that develops postoperatively may be just as hazardous as intraoperative hyperthermia. Temperatures exceeding 38.5°C are common during the first 48 hours after cardiac surgery and occur in nearly 40% of patients.[293] This postoperative hyperthermia is known to be correlated with increased cognitive dysfunction 6 weeks after cardiac surgery.[294] Therefore, hyperthermia in the postoperative period should be treated with antipyretics and, if necessary, active body surface cooling.

In summary, patients maintained on CPB should be rewarmed early and slowly. No monitored temperature should be allowed to exceed 37.0°C.[292] This practice prevents cerebral overheating.

Blood Gas Management

Temperature has a significant effect on the solubility of gases in solution. Specifically, in blood gas analysis, the carbon dioxide concentration (and consequently the pH) is profoundly altered by changes in temperature. As temperature decreases, the partial pressure of arterial carbon dioxide ($Pa{CO_2}$) decreases as carbon dioxide becomes more soluble in plasma. Therefore, inducing hypothermia during CPB poses a dilemma in terms of how best to approach acid-base management at lower temperatures (i.e., whether *temperature-corrected* or *temperature-uncorrected* blood gas values should be used to manage the patient's care). This question has been the basis for a decades-old debate: α-stat versus pH-stat blood gas management (Table 54.12).

α-Stat Hypothesis. In aqueous systems, neutrality (pN) is said to occur when $[H^+] = [OH^-]$. The dissociation of water depends on temperature; therefore, the pH value at which pN occurs varies with the temperature. Acid-base comparative physiologic studies of animals whose blood temperature varies (i.e., ectotherms and poikilotherms) suggest that blood and intracellular pH values parallel the temperature-related changes seen in the neutrality of water.[295] From these findings emerged the α-stat strategy, which endeavors to maintain intracellular electrochemical neutrality across all temperatures.

Maintaining this neutrality requires an appropriate buffering system. It is thought that protein buffering is largely responsible for maintaining this temperature-pH relationship. Specifically, the imidazole group of the amino acid histidine has a dissociation constant (p*Ka*) value similar to that of blood. Therefore, if carbon dioxide stores are held constant during cooling, the ionization state (termed α) will remain constant. This may be important because the ionization state affects both the structure and the function of proteins. Keeping the charge state constant (α-stat) by allowing blood pH to change with the neutrality of water is thought to be essential for maintaining the most physiologically beneficial structure and function of enzymes during hypothermia. Research suggests that when the α-stat strategy is used, cerebral autoregulation remains largely intact until deep hypothermic temperatures are reached.[296]

To manage acid-base balance during hypothermic CPB by using the α-stat approach, one must maintain temperature-*un*corrected blood gas values. The term *un*corrected is often confusing because it refers to the values that the blood gas machine typically reports without being programmed to correct the values to the actual temperature of the patient. For example, blood drawn from a patient undergoing CPB at 18°C is measured in a blood gas machine, which anaerobically warms the sample to 37°C and reports values at normothermia. With α-stat management, one would strive for normal temperature-uncorrected results, which would theoretically maintain intracellular electrochemical neutrality.

pH-Stat Hypothesis. An alternative strategy is the pH-stat approach to acid-base management. The pH-stat strategy endeavors to maintain a constant pH despite changes in temperature. Hibernating animals tend to follow this strategy. To counter the tendency of cooling blood to follow the neutrality of the water curve and become more alkalotic as temperature decreases, these animals increase their blood carbon dioxide content and maintain normal pH at hypothermic body temperatures.

Carbon dioxide is a potent cerebral vasodilator; therefore, the increase in carbon dioxide content during pH-stat management uncouples cerebral autoregulation; cerebral blood flow increases independent of cerebral metabolic demand. These effects are thought to be neuroprotective for infants maintained on CPB who may have aortopulmonary collateral vessels and also to promote deep homogeneous cooling of the brain before circulatory arrest.[297] However, during rewarming, the higher cerebral blood flow that results from using pH-stat management may increase the embolic load sent to the brain.

Using the pH-stat strategy with CPB involves managing blood gas parameters with temperature-*corrected* values by programming the blood gas machine to correct the values to the patient's body temperature. During bypass, decreasing blood temperature increases the solubility of carbon dioxide and, consequently, results in decreased $Pa\text{CO}_2$ values. Therefore, the perfusionist must either decrease the "sweep speed" of the air-oxygen mixture or, less commonly, add carbon dioxide to the oxygenator ventilation system to increase the carbon dioxide content and maintain a $Pa\text{CO}_2$ of 40 mm Hg (and normal pH) as the temperature of the blood decreases. The extracorporeal circuitry must be equipped with an in-line blood gas analyzer so that $Pa\text{CO}_2$ levels can be continually monitored during CPB.

Which Strategy Is Best?. In adult patients, several independent, prospective randomized trials have shown that using α-stat management during moderate hypothermia produces better neurologic outcomes than observed with pH-stat management. These and other data have led to an evidence-based recommendation (ACC/AHA class I, level A) that α-stat management be used in adults undergoing moderate hypothermic CPB.[288,298] It is unclear which strategy is superior in adults when deep hypothermia is used with or without circulatory arrest.

In pediatric CPB, however, several human and animal studies suggest that pH-stat management may be more beneficial than α-stat management for infants. These studies showed that pH-stat management produced more homogeneous cooling, less oxygen consumption, and better cerebral metabolic recovery than did α-stat management. The clear trend in pediatric CPB is to use pH-stat alone or in combination with α-stat (i.e., to use pH-stat during cooling and α-stat during rewarming) when deep hypothermia is used.[299]

Inflammatory Response to Cardiopulmonary Bypass

Since the 1980s, much has been written about the rapid and profound inflammatory response that CPB elicits. Surgical stress itself causes an inflammatory response, which CPB aggravates by subjecting the patient's blood to contact with foreign surfaces, ischemia and reperfusion, and gaseous and particulate microembolization, which initiate and amplify multiple redundant and interconnected immune cascades. With the onset of CPB, the increased expression of *initiator* substances (including endotoxin, tumor necrosis factor [TNF], and nuclear factor κB, as well as anaphylatoxins and cytokines) stimulates *effector* cells (including polymorphonuclear neutrophils, platelets, and endothelial cells) to upregulate adhesion molecules and release cytotoxic oxygen radicals and proteases. This response can produce tissue injury of varying degree in a variety of organ systems.

Numerous clinical approaches have been shown to reduce the inflammatory response measurably in cardiac surgical patients (Fig. 54.17). These approaches can be loosely grouped into three primary categories: modification of surgical and perfusion techniques, modification of circuit components, and pharmacologic strategies.

Modification of Surgical Techniques or Perfusion Techniques

Modification of Surgical Technique. The movement toward minimally invasive cardiac surgery is at least partly motivated by the goal of reducing inflammation in the patient. The term *minimally invasive* may refer to procedures that use modified surgical techniques, including miniature incisions with or without robotic assistance, and to procedures that use classic surgical approaches that minimize or eliminate the use of CPB and thus exposure to the ECC (e.g., OPCAB). Although OPCAB does not eliminate the patient's inflammatory response, it may produce less expression of inflammatory cytokines than does CABG with CPB.[300] However, it may be that the OPCAB-related reduction in inflammation is minimal in the days after the surgical procedure.[301] Moreover, any improvements in outcomes that

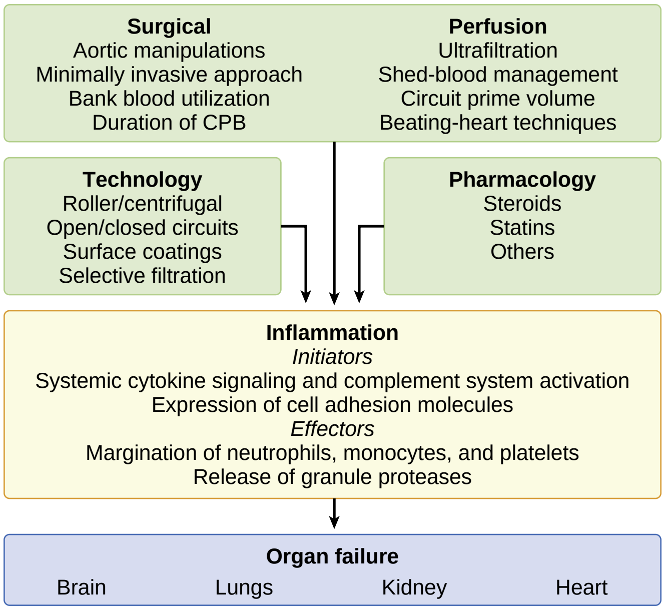

Fig. 54.17 Brief review of the current understanding of the many variables that influence the inflammatory response in patients undergoing cardiopulmonary bypass *(CPB)*.

may be attributable to the use of OPCAB instead of standard CABG are probably not exclusively caused by elimination of the ECC. Rather, minimizing or eliminating aortic manipulation, particularly in patients with severe atherosclerosis, may independently reduce the incidence of stroke.[43]

Modification of Perfusion Techniques. Reasons for the lack of consensus on the exact contribution of CPB to the inflammatory process include the issue that perfusion practice is far from standardized.[298] Various perfusion techniques and technologies have been shown to reduce inflammation, including shed-blood management,[302] ultrafiltration,[303,304] temperature management,[285] circuit miniaturization,[305,306] and on-pump beating-heart techniques.[307]

Perfusion Technology

In addition to the ways in which perfusion technology is used, the type of technology used may moderate the inflammatory response to CPB. No consensus exists regarding which arterial pump technology—roller pumps or centrifugal pumps—is less hemolytic. Some investigators have shown that using modified surface materials in the CPB circuit, such as heparin coatings, may reduce inflammation.[308-310] Additionally, selective filtration of leukocytes with an in-line leukocyte filter has been proposed as a method for reducing the concentration of activated leukocytes and inflammation. Warren and associates,[311] in a review of 63 studies, concluded that leukocyte filtration may have some modest benefits, but definitive evidence of any improvement in inflammatory-mediated complications is insufficient. Additionally, hemoconcentrators may be able to remove inflammatory mediators from circulation through large-volume zero-balance ultrafiltration techniques,[304] but little evidence exists of significant clinical improvements in the adult CPB population.

Pharmacologic Strategies

After decades of laboratory studies and clinical trials, a rigorously vetted pharmacologic approach to reducing inflammation in CPB-supported patients is still lacking. The best-established drug, aprotinin, was removed from the market in 2007 because of concerns about an increased risk of acute kidney failure after administration.[119] Thus, the clinician is left to select from a short list of drugs whose use is supported only by mixed mechanistic results and insipid evidence of improved clinical outcomes.

Corticosteroids have been used in cardiac surgery for decades for their immunosuppressive and antiinflammatory effects. The results of meta-analyses of small randomized clinical trials of methylprednisolone or dexamethasone have yielded conflicting results.[312,313] These drugs may reduce the incidence of atrial fibrillation, but they may also increase gastrointestinal bleeding, and they did not influence postoperative mortality or cardiac or pulmonary complications.[312,313] The first large (4494 patients) randomized controlled clinical trial of the use of routine corticosteroids during cardiac surgery in adults showed that high-dose (1 mg/kg) dexamethasone did not reduce the 30-day incidence of major adverse events (death, MI, stroke, renal failure, or respiratory failure).[314]

One meta-analysis of randomized controlled studies of the use of prophylactic preoperative statins to reduce inflammatory mediators concluded that evidence indicates that statins reduce plasma concentrations of IL-6, IL-8, TNF-α, and CRP when doses of 20 to 80 mg/day are administered for 1 day to 3 weeks preoperatively.[315] In a Cochrane Database review of 11 randomized controlled trials performed in patients undergoing on- or off-pump cardiac surgical procedures, pooled analysis showed that statin pretreatment before surgery reduced the incidence of postoperative atrial fibrillation and was associated with a shorter length of stay in the ICU but failed to influence mortality.[316] Finally, a meta-analysis of 14 studies of ketamine, which may also have antiinflammatory effects, suggests that ketamine administration significantly reduces the IL-6 response to surgery.[317]

DEEP HYPOTHERMIC CIRCULATORY ARREST

DHCA involves reducing the patient's core temperature to profoundly hypothermic levels (15°C-22°C) before globally interrupting blood flow to the body, draining all the blood out of the patient, and collecting it in the ECC reservoir. In adults, this procedure is primarily used during surgical repair of the aorta, especially in cases of dissection or aneurysm involving the transverse arch.

Deliberate hypothermia with systemic cooling is the only reliable method of neuroprotection during complete global ischemia. Some clinicians also put ice bags on the patient's head to augment or maintain cerebral cooling. Pharmacologic approaches to neuroprotection, such as administering steroids to reduce inflammation or barbiturates or propofol to induce burst suppression, are used in some centers, although evidence to support their efficacy in the setting of complete global ischemia is scant. Furthermore, if the EEG is monitored, it is important to induce EEG isoelectricity with hypothermia before commencing the period of circulatory arrest rather than relying on supplemental barbiturates or propofol to provide neuroprotection.[318]

The equipment and circuitry of the heart and lung machine used for DHCA procedures are not generally different from those used for standard CPB procedures. Blood gas management during cooling and rewarming for DHCA procedures typically follows the α-stat management scheme in adult patients and the pH-stat management scheme in pediatric patients (see the earlier section on blood gas management). Systemic cooling is begun when CPB is initiated and is continued until the temperature of the patient is low enough to provide adequate protection for the anticipated duration of circulatory arrest. When deciding what temperature is "adequate," one must give top priority to protecting the brain. Because no clinically feasible method for measuring brain temperature is available, surrogate temperatures must be used to estimate core temperature (see the earlier section on temperature). A time lag exists between the time that arterial blood reaches a target temperature and the time that the brain's parenchymal tissue equilibrates with the blood temperature. Consequently, when aggressive cooling is used, arterial blood temperature underestimates brain temperature. For an average-sized adult, cold arterial perfusion at full CO flow should be continued for 20 to 30 minutes after the "goal" arterial blood temperature is reached to ensure that the brain has had sufficient time to cool. For an anticipated circulatory arrest period of 30 to 40 minutes, a temperature of 18°C to 20°C is probably adequate; however, slightly warmer temperatures may be acceptable if a shorter period of arrest is used or if cerebral perfusion is maintained.[319] It is also good practice to monitor temperatures at multiple sites on the patient, in addition to blood temperature, to observe the relative change over time during cooling and rewarming. Furthermore, the EEG provides a good pharmacodynamic endpoint for the cerebral effects of cooling; hypothermia-induced EEG isoelectricity should be present before elective circulatory arrest commences.[319]

As the patient cools, the viscosity of blood will increase. At a temperature of 18°C, the viscosity of blood with a hematocrit of 30% to 35% increases to three to four times its normal level. Cardiac surgical textbooks suggest that hemodilution is important in minimizing any microcirculatory disturbances that may occur because of increased blood viscosity. Consequently, some clinicians may target a hematocrit value that is appropriate to the patient's temperature during DHCA, approximately 18% to 20%. However, the results of a study performed in piglets by Duebener and colleagues suggested that a hematocrit of 30% is preferable if DHCA is used.[320]

When the patient has reached an appropriate core temperature as determined by temperatures measured at multiple sites and after adequate time for equilibration, the arterial blood flow from the pump is stopped, and the patient's blood is drained into the ECC reservoir. During the period of circulatory arrest, the blood in the ECC reservoir should be recirculated to prevent stasis and maintain the desired temperature. Gas flow to the oxygenator should be discontinued to prevent profound hypocapnia. Reperfusion should be initiated with cold blood. An initial period (5-10 minutes) of cold reperfusion may enhance cerebral protection by removing accumulated metabolic products from the cerebral capillary beds while maintaining a low cerebral metabolic rate of oxygen.

The risk of neurologic injury after cardiac surgery involving DHCA extends into the postoperative period because cerebral vascular resistance is increased and cerebral blood flow is decreased for several hours after the procedure. In addition, hyperthermia, possibly secondary to a systemic inflammatory response, is common in the postoperative period and should be treated aggressively.

In an effort to reduce the period of cerebral ischemia during circulatory arrest, selective cerebral perfusion techniques have been developed. Selective antegrade cerebral perfusion can be accomplished by directly cannulating the left common carotid artery,[321] or perfusion can easily be delivered through the right common carotid artery when the aortic cannulation approach for CPB involves cannulating the axillary or innominate artery.[322] Axillary cannulation facilitates the delivery of arterial blood from the ECC to the entire circulatory system during cooling and rewarming or, with the addition of a clamp to the proximal innominate artery, selectively into the right common carotid and radial arteries. Because of the proximity of the arterial cannula to the right radial artery, arterial blood pressure monitored in the right radial artery may be significantly higher than pressure monitored in the left radial or femoral artery. Consequently, right radial arterial pressure should not be used to control perfusion during cooling and rewarming. During delivery of selective antegrade cerebral perfusion, cold arterial blood from the extracorporeal circuit should be delivered to maintain the cerebral blood pressure between 30 and 60 mm Hg. The perfusion flow rates necessary to achieve this pressure vary depending on the site or sites of arterial cannulation. Direct cannulation of only the left common carotid artery requires the least flow, whereas cannulation of multiple head vessels or of the axillary artery (which perfuses the right common carotid, right internal thoracic artery, and right arm) requires higher flow rates. Subsequently, flow rates of 150 to 1500 mL/min have been reported. Selective retrograde cerebral perfusion is delivered through a snared cannula introduced into the right atrium and advanced into the SVC; this type of perfusion can be initiated after the patient's systemic perfusion is discontinued. Cold oxygenated blood from the ECC can be administered at a flow rate (≈5 mL/kg/min) high enough to maintain SVC pressure between 35 and 40 mm Hg.[323] Although some debate remains about whether selective cerebral perfusion of any kind is necessary to achieve optimal neurologic outcome after DHCA procedures,[324] investigators generally agree that antegrade cerebral perfusion, when used properly, is superior to retrograde perfusion.[325,326]

LEFT HEART BYPASS

If a descending aortic aneurysm or aortic dissection is to be surgically replaced with a tube graft, blood flow through the patient's thoracic aorta must be interrupted. The application of vascular clamps to this major vessel acutely increases the afterload of the heart and produces global ischemia in all parts of the body distal to the clamp. Patients with compromised cardiac function or those undergoing a surgical procedure in which the duration of ischemia will be unacceptably long require some method of circulatory support. Temporary interposition of a shunt (e.g., a Gott shunt) around the area of repair is the simplest approach, but it does not offer the level of support that can be achieved with LHB or CPB.

For these procedures, the approach is usually through a left thoracotomy incision, which provides excellent access to the left atrium. The simplest approach to LHB is to withdraw blood from the left atrium with a centrifugal pump and return the blood to the patient's femoral artery. This *simple* LHB circuit gives the clinician excellent control of blood flow distal to the clamps and therefore the ability to manipulate the afterload against which the heart must work. However, the complexity of some surgical procedures requires that full CPB be used.

Surgical complications are not uncommon in these patients and include hypoxia, hypothermia, and exsanguination. A double-lumen endotracheal tube or bronchial blocker is often used to isolate the left lung from the right. After left thoracotomy and exposure of the aneurysm, ventilation of the left lung is discontinued. Patients with preexisting lung dysfunction or traumatic lung injury associated with aortic dissection may have difficulty maintaining oxygenation with a single lung. Because of the large surgical exposure required and the sometimes extended duration of the procedure, it is not unusual for the patient to become hypothermic. Furthermore, these procedures carry an elevated risk of blood loss and the consequent need for rapid replacement of fluids and blood products. It is often advisable to use *complete* LHB to reduce these risks. Currently the use of LHB has decreased in clinical practice because of the widespread application of endovascular techniques for the treatment of descending aorta pathologies.

Fig. 54.18 illustrates the simple-circuit and complete-circuit approaches to LHB. The major difference between a complete LHB circuit and the standard CPB circuit is the position of the reservoir in the circuit and the position of the venous cannula in the patient. In a complete LHB circuit, the reservoir does not receive the blood returning from the patient as in the CPB circuit. With the reservoir out of the pathway of the blood, the effective surface area of the ECC is reduced; this reduction attenuates contact activation of the blood and minimizes the need for high-dose heparinization.

In both circuits, the management goal is the same—to keep arterial blood pressure higher than 60 mm Hg both proximal and distal to the aortic cross-clamp throughout the procedure. However, the complete LHB circuit gives the clinician the ability to manage hypoxia, hypothermia, and blood loss. The addition of an oxygenator to the circuit makes it possible to augment the patient's ventilation and oxygenation. The heat exchanger is used to maintain normothermia. The reservoir facilitates the addition of large volumes of fluid or blood products in the event of hemorrhage, hypovolemia, or both.

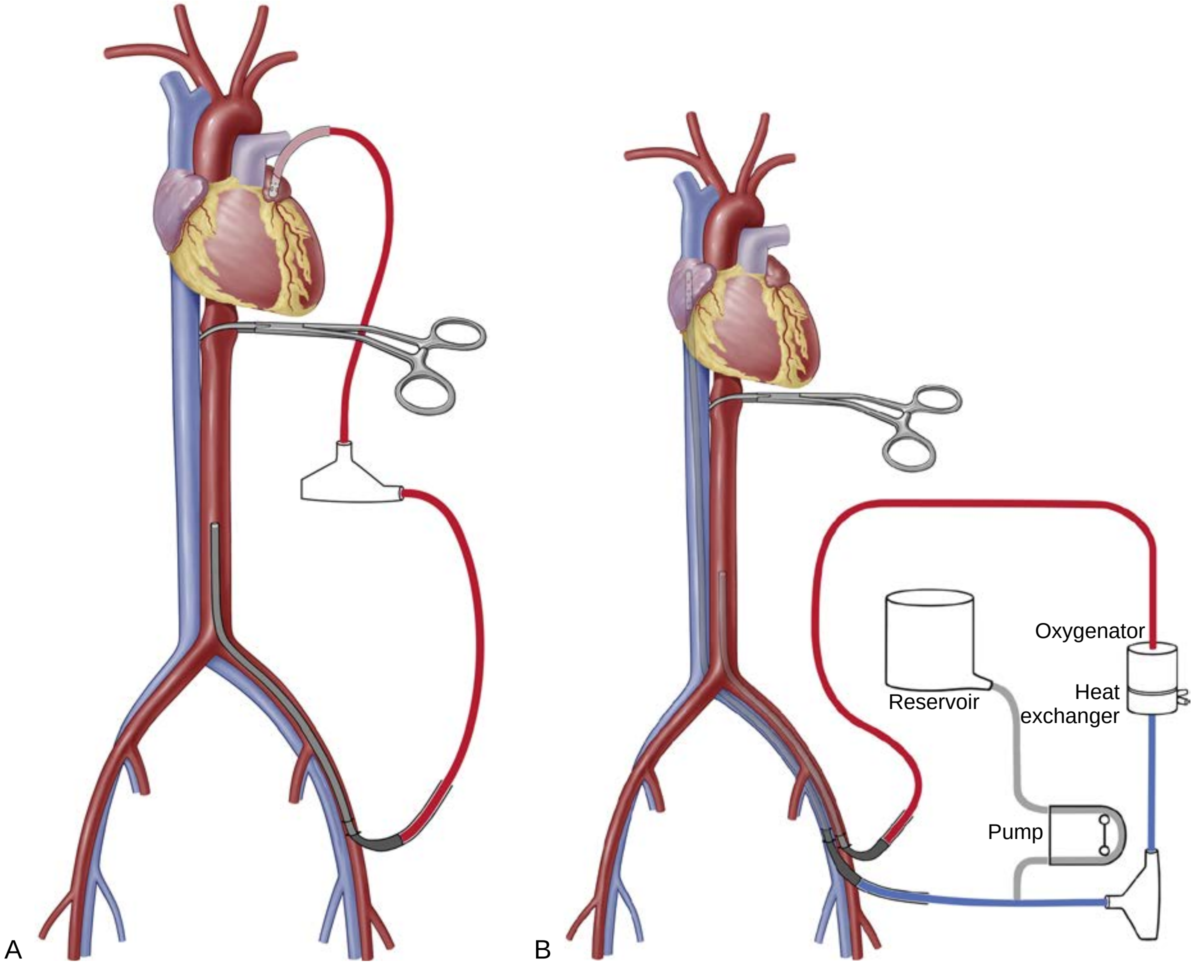

Fig. 54.18 Left heart bypass (LHB) diagram. (A) Simple LHB (left atrium, cone, and femoral artery). (B) Complex LHB (including an oxygenator, heat exchanger, and reservoir for fluid administration).

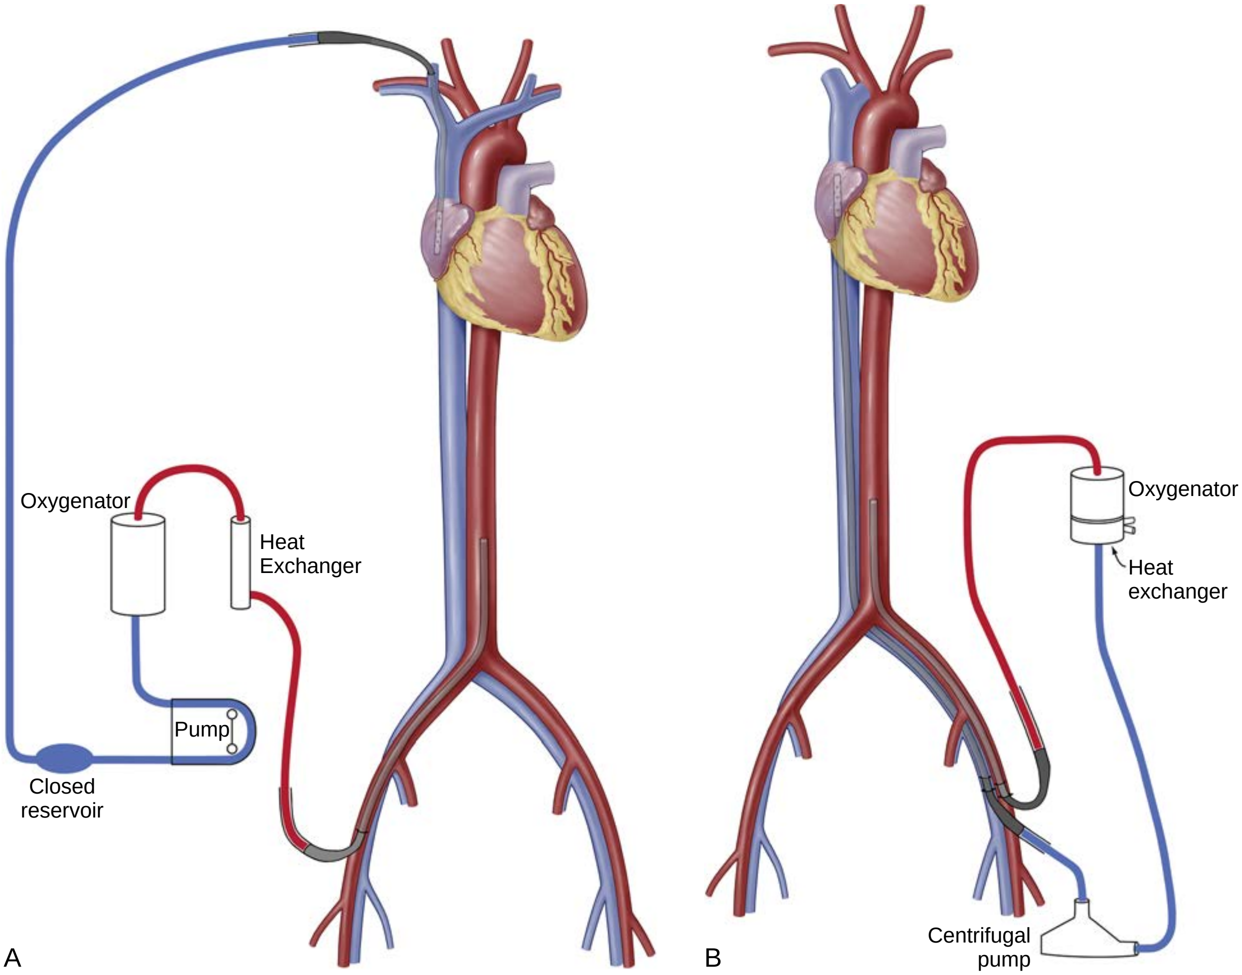

Fig. 54.19 (A) Patient cannulated through the internal jugular vein and femoral artery, with a traditional extracorporeal membrane oxygenation circuit. (B) Patient cannulated through the femoral vein and femoral artery, with a simple cardiopulmonary support circuit.

CARDIOPULMONARY SUPPORT AND EXTRACORPOREAL MEMBRANE OXYGENATION CIRCUITS

For all practical purposes, no difference exists between a CPS circuit and an ECMO circuit. Both consist of a CPB circuit without a reservoir, an arterial line filter, or any of the ancillary pumps that are used during cardiac surgery (i.e., pump suction, vent, and cardioplegia). Because the reservoir is removed from the circuit, these systems are considered closed. Closed circuits have a static internal volume and cannot unload the patient's vascular system.

The removal of the reservoir and filters from the circuit has advantages and disadvantages. The chief advantage is that the surface area of the circuit is significantly reduced, which facilitates a reduced anticoagulation regimen with an initial heparin dose of 75 to 150 units/kg and a continuous infusion of heparin at 25 to 75 units/kg/h to maintain ACTs of 180 to 250 seconds.[†]

The chief disadvantage is that the closed circuits are less able to trap emboli. Special precautions should be taken when connecting a closed ECC to the patient's cannulas, injecting fluids and medications into the circuit, or sampling from the venous line. Additionally, because of the reduced anticoagulation regimen, blood stasis in the circuit should be avoided, and periods of low flow should be minimized.

In intensive care settings, ECMO or CPS is used to support the heart, lungs, or both for days or weeks. The newer generation of centrifugal pumps and hollow-fiber oxygenators perform acceptably well during these long-term applications and are becoming more commonly used in desperate situations (Fig. 54.19).

Specific Cardiovascular Disease States

CORONARY ARTERY DISEASE

Pathophysiology of Coronary Disease

Coronary Anatomy. Understanding the coronary anatomy is important to understand the pathophysiology of CAD and the anesthetic care of patients undergoing myocardial revascularization. Two main coronary arteries take off from the aorta and supply the myocardium: the left main coronary artery (LMCA) and the RCA. The LMCA subsequently divides into the left anterior descending (LAD) coronary artery and the left circumflex artery (LCx). The LAD courses down the interventricular groove and gives rise to the diagonal and septal branches. The diagonal branches of the LAD supply the anterolateral aspect of the heart. The septal branches supply the interventricular septum, as well as the bundle branches and the Purkinje system. The LAD itself terminates at the apex of the LV. The other branch of the LMCA, the LCx, courses along the left AV groove and gives rise to one to three obtuse marginal branches that supply the lateral wall of the LV. In 45% of patients, the sinus node arterial supply arises from the LCx. In 15% of patients, the LCx gives rise to the posterior descending artery, which supplies the posterior inferior aspect of the LV ("left-dominant" system).

[†] For Extracorporeal Life Support Organization (ELSO) anticoagulation guidelines see https://www.elso.org/Portals/0/Files/elsoanticoagulationguideline8-2014-table-contents.pdf

The RCA traverses the right AV groove and supplies the right anterior wall of the right ventricle through its acute marginal branches. In 85% of the population, the RCA gives rise to the posterior descending artery supplying the posterior inferior aspect of the LV ("right-dominant" system). The AV node arterial branch arises from the dominant artery to supply the node, the bundle of His, and the proximal part of the bundle branches. In addition, in 55% of the population, the sinus node arterial supply arises from the RCA.

Determinants of Myocardial Oxygen Supply and Demand. The balance of oxygen supply versus demand is somewhat complex (Figs. 54.20 and 54.21). Oxygen supply is determined by the oxygen content of arterial blood and by coronary blood flow. Extraction of oxygen from arterial blood is maximal at rest. As demand increases (with exercise or hemodynamic stress), the oxygen supply to the myocardium must also increase.

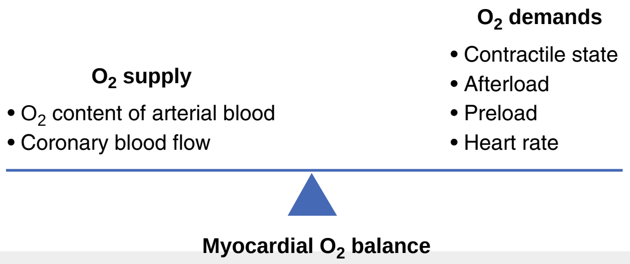

Fig. 54.20 **Factors determining myocardial oxygen (O_2) supply and demand.** (From Mittnacht AJC, Weiner M, London MJ, et al. Anesthesia for myocardial revascularization. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:524.)

Determinants of blood flow in normal coronary arteries include the pressure differential across the coronary bed (i.e., the coronary perfusion pressure) and coronary vascular resistance. The coronary perfusion pressure for the LV is the aortic blood pressure during diastole minus the LV end-diastolic pressure (LVEDP); thus, elevations in LVEDP impede subendocardial blood flow. Because coronary stenosis causes vessels to dilate maximally distal to the stenosis, manipulating coronary perfusion pressure is an important means of controlling coronary blood flow (and preventing or treating myocardial ischemia). However, because the determinants of myocardial oxygen balance interact in a complex manner, altering any one of them can have multiple effects. For example, a rise in blood pressure increases coronary blood flow but also increases afterload, thereby elevating wall tension and oxygen demand.

The duration of diastole is another important factor affecting oxygen supply to the myocardium because 70% to 80% of coronary arterial blood flow occurs during the diastolic phase of the cardiac cycle. During the systolic phase, cardiac contraction increases intraventricular cavitary pressure and coronary vascular resistance, thus impeding myocardial perfusion. The total time per minute spent in diastole is a function of the heart rate, but a nonlinear relationship exists between heart rate and the duration of diastole (Fig. 54.22). This is a major reason for the use of β-blockers as antiischemic drugs, both for long-term therapy and for preventing even small increases in heart rate during the perioperative period.

The oxygen content of blood depends on hemoglobin-bound oxygen and, to a lesser extent, dissolved oxygen. Although a high hemoglobin level gives the blood high oxygen-carrying capacity, the minimum level of hemoglobin necessary to avoid ischemia has not been well defined in clinical studies. Factors that affect this limit include the severity of CAD, the heart rate, perfusion pressure, and myocardial wall thickness and tension. Furthermore, delivery of oxygen to myocardial tissue also depends on a high partial pressure of oxygen (PO_2), and actual release of oxygen from hemoglobin occurs according to the oxyhemoglobin

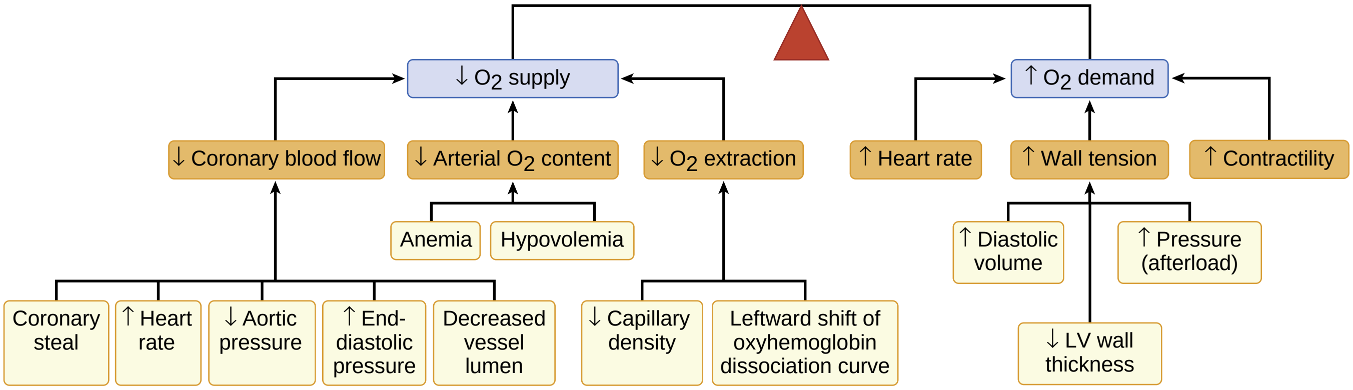

Fig. 54.21 **Summary of factors that affect myocardial oxygen supply and demand.** ***LV,*** **Left ventricular.** (From Green MS, Okum GS, Horrow JC. Anesthetic management of myocardial revascularization. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia.* 5th ed. dissociation curve. A leftward shift of this curve caused by alkalosis, hypothermia, or low levels of 2,3-diphosphoglycerate decreases the release of oxygen.

In patients undergoing myocardial revascularization, reductions in myocardial oxygen supply may occur because of hypotension, tachycardia, anemia, or coronary vasoconstriction, as well as increases in demand secondary to tachycardia or increased afterload. Although myocardial ischemia is certainly possible without any changes in systemic hemodynamics, vigilant monitoring for imbalances in myocardial oxygen supply versus demand, as well as monitoring for the development of ischemia, is necessary throughout the perioperative period. Myocardial ischemia may be detected by ECG monitoring and ST-segment analysis, as well as by TEE monitoring for the development of regional wall motion abnormalities.

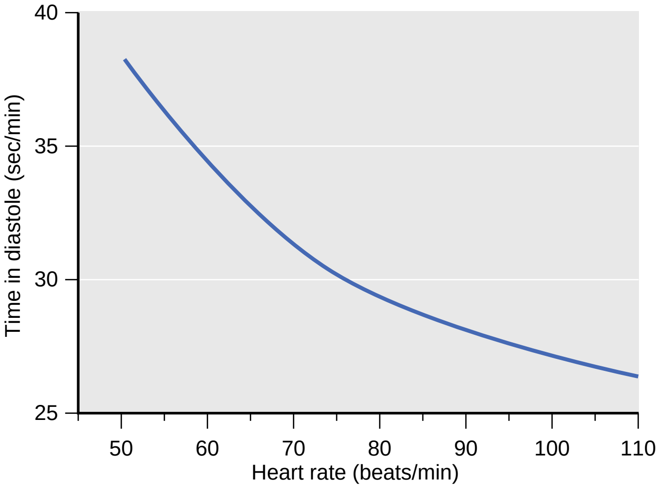

Fig. 54.22 Total time spent in diastole each minute plotted as a function of heart rate in beats per minute. The reduction in diastolic interval leads to diminished left ventricular blood flow as heart rate increases. (From Green MS, Okum GS, Horrow JC. Anesthetic management of myocardial revascularization. On-Pump Coronary Artery Bypass Grafting Surgery

Preoperative Evaluation. Typically, patients undergoing CABG have had extensive preoperative assessment of their cardiac disease (see Chapter 31). Coronary artery anatomy should be noted, particularly a high-grade lesion in the LMCA or proximal LAD coronary artery or triple-vessel disease. Ventricular function, assessed by angiography or echocardiography, is usually recorded as an estimated EF. Other cardiac disease discovered in the preoperative workup should be noted and understood, including valvular abnormalities such as concurrent MR, aortic stenosis (AS), aortic insufficiency, atrial septal defect (ASD) or ventricular septal defect (VSD), or ventricular aneurysm. The anesthesiologist should be aware of any abnormal cardiac rhythm on the ECG or noted in the history, such as atrial fibrillation or other supraventricular tachycardia (which may lead to hemodynamic instability or increase the patient's risk of an embolic neurologic complication), left bundle branch block or a prolonged PR interval (which may progress to a more advanced heart block), or complete heart block, which may be underlying a paced rhythm. Antiarrhythmic therapy, with either pharmacologic drugs or devices such as a pacemaker or automated implantable cardioverter-defibrillator (ICD), should be noted.

Various models for assessing overall risk have been developed that include certain factors associated with increased risk: poor LV function (history of CHF or LVEF <30%), advanced age, obesity, emergency surgery, combined procedures (e.g., valve repair or replacement combined with CABG), prior cardiac surgery, and history of diabetes or renal failure (Table 54.13).[327,328]

Premedication. In the current era, cardiac surgical patients often have same-day admissions. Frequently, the only premedication they receive is midazolam on the morning of the surgical procedure, to allay anxiety. However, small additional doses of midazolam, fentanyl, or both may be administered during line placement, especially if the central line is placed before the induction of general anesthesia (see the section on induction of anesthesia and the

LV, Left ventricular.

Modified from Green MS, Okum GS, Horrow JC. Anesthetic management of myocardial revascularization. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:293–318.

prebypass period); this may be particularly important in patients with CAD, to minimize undesirable sympathetic stimulation that could cause tachycardia and hypertension. However, administration of these drugs should be incremental and judicious in patients with low CO or significant pulmonary hypertension.

Induction and maintenance of anesthesia. No single anesthetic agent or combination of anesthetic drugs is suitable for anesthetic induction and maintenance in every patient undergoing CABG surgery. Induction of anesthesia for coronary revascularization is often achieved by administering a benzodiazepine (typically midazolam) in combination with a narcotic, usually fentanyl, and a muscle relaxant.[328] However, either etomidate or propofol in combination with a narcotic has frequently been used. The goal is to avoid wide swings in hemodynamics with induction and with subsequent intubation. Typically, volatile agents are used throughout the prebypass, bypass, and postbypass periods. In addition, the volatile anesthetics have several cardioprotective effects, including triggering the preconditioning cascade and mitigating reperfusion injury.[146] Additional midazolam may be given to ensure that intraoperative awareness is avoided.

One factor in the choice of specific anesthetic agents and doses is the patient's preexisting LV function. Patients with normal LV function can have a significant sympathetic response to surgical stimulation that results in hypertension and tachycardia. Use of β-blockers, additional propofol, higher doses of a volatile anesthetic agent, or vasodilators may be warranted if this situation develops. Conversely, in patients with poor LV function, hypotension may develop with the administration of anesthetic agents because of a reduction in CO or vasodilation, or both. Such patients may require vasopressor or inotropic pharmacologic support, or both.

Another factor in the choice of anesthetic agent is the possibility of early extubation within 4 to 6 hours of arrival in the ICU (so-called fast tracking). Patients who have good preexisting cardiac function and who will be undergoing CABG as an isolated procedure are usually candidates for fast tracking. This strategy necessitates the use of agents in dosages that would not keep the patient sedated or render the patient unable to ventilate adequately for a prolonged period. Early extubation may not be appropriate in patients with poor cardiac function, severe pulmonary disease, or obesity or in those undergoing emergency procedures, CABG combined with other procedures, or redo operations.

Monitoring. Monitoring for patients scheduled to undergo coronary revascularization surgery has evolved since the 1960s, in an effort to detect intraoperative ischemia. The standard American Society of Anesthesiologists (ASA) monitors and invasive arterial blood pressure monitoring (with noninvasive blood pressure backup) are always used. Typically, both leads II and V_5 are used for continuous monitoring, as well as automated ST-segment analysis to improve the chances of detecting ischemia.[329]

PA catheters are used less commonly now than in the past because several studies have shown that using such catheters does not improve outcome.[330] In fact, the risks inherent in the use of these catheters may actually exceed the benefits.[24] Certainly, the absolute PAP is not diagnostic of ischemia, although waveform changes may be more predictive. For example, the appearance of a new V wave on the PCWP tracing indicates ischemic papillary muscle dysfunction. In addition, specialized PA catheters allow derivation of several indices of cardiac function, including CO, cardiac index, and $S\bar{v}O_2$. Furthermore, some clinicians believe that the PA catheter is useful in the postoperative period when TEE is not available for continuous monitoring of the patient. In summary, use of the PA catheter for routine CABG surgeries has devolved over the years due to risks inherent in misuse of the information that the catheter provides. Practitioners in individual institutions have developed preferences and policies regarding the use of PA catheters in cardiac surgery. Use of the PA catheter mandates that a risk-benefit assessment be made for each individual patient when placing these catheters.

Regional wall motion abnormalities detected by TEE are more sensitive to ischemia than ECG changes or PA catheter waveform and pressure changes.[329] TEE can be used to interrogate regions of the heart representative of all three major coronary arteries simultaneously. This technology is commonly used throughout revascularization procedures to assess regional wall motion by qualitative inspection of radial shortening and wall thickening, and it is particularly useful after revascularization. In addition, TEE is used to assess ventricular preload and contractility, diagnose any valvular abnormalities, evaluate calcific and atherosclerotic lesions at the aortic cannulation sites, and detect LV thrombus and uncommon congenital abnormalities (e.g., ASD or VSD, persistent left SVC). See Chapter 37 for details on the perioperative use of TEE.

Surgical Considerations. Conventional (on-pump) CABG is the most commonly performed procedure in cardiac surgery. A full median sternotomy performed with a sternal saw is standard. Ventilation of the lungs is halted briefly during sawing of the sternum to avoid a pleural tear. An oscillating saw may be used in patients with a previous sternotomy (redo). The risks posed by redo sternotomy include perforation of the right ventricle, damage to existing vein grafts, and ventricular fibrillation from the transmission of electrocautery energy through preexisting sternal wires. Therefore, PRBCs (2 units) should be immediately available, and external defibrillation pads should be positioned before preparation and draping. Furthermore, surgical manipulation of previous vein grafts may result in embolization of atheroma and resultant ischemia. If a complication does occur during sternotomy or exposure of the heart and cannulation sites, emergency bypass may be established by cannulating a femoral artery and vein.

If an IMA is to be used, the surgical table is elevated and often rotated somewhat to the left to facilitate surgical comfort in performing the dissection. Tidal volumes are also reduced to facilitate exposure. Heparin administration usually occurs before the IMA pedicle is clamped, and papaverine may be injected into this vessel. The prebypass period for on-pump CABG may be relatively short (<1 hour) or may require several hours for dissection of the left IMA, right IMA, radial arteries, or any combination of these vessels. In addition, for most CABG procedures, adequate venous conduits must be harvested, and endoscopic saphenectomy is now common.

Before aortic cannulation, TEE or epiaortic echocardiography, or both, provides critical information regarding the presence and precise location of calcification or mobile atheromas in the aortic arch. The surgeon may request TEE guidance for placement of the retrograde catheter into the coronary sinus; furthermore, if a persistent left SVC is diagnosed, this abnormality may render retrograde cardioplegia problematic.[328] After CPB is initiated, TEE may also be used to ensure correct placement of the LV vent, as well as to verify the absence of LV thrombus in patients with a recent anterior wall MI or aneurysm.

Surgical and technical complications of CABG surgery that manifest as ischemia include (1) poor-quality proximal or distal anastomoses of the grafts, (2) inadvertent incision of the coronary back wall leading to coronary dissection, (3) suturing of the coronary artery closed, (4) inadequate vein graft length resulting in stretching of the vein when the heart is filled, (5) excessive vein graft length leading to kinking of the vein, and (6) vein graft thrombosis.[327] CPB may need to be reinstituted to correct surgical causes of ischemia after revascularization. Heparin should be immediately available if emergency reinstitution of CPB becomes necessary.

After bypass, other causes of ischemia include (1) incomplete revascularization resulting from ungraftable vessels or diffuse distal disease, (2) coronary embolization of air or atheromatous debris, (3) coronary spasm, (4) mechanical factors such as vein graft stretching or occlusion of IMA flow secondary to overinflation of the lungs, and (5) thrombus formation.[327] The treatment of ischemia includes administering various drugs: nitroglycerin or vasopressors when SVR is either high or low; nitroglycerin, a calcium channel blocker (diltiazem, nifedipine, or nicardipine), or both to treat coronary spasm; a vasoconstrictor (usually phenylephrine) to "push" intracoronary air through the vasculature when air embolism is suspected; a β-blocker (usually esmolol) to treat tachycardia; and one or more inotropic agents to increase CO if necessary. In addition, AV sequential pacing may be used to improve rate, rhythm, and hemodynamic stability when appropriate. At times, mechanical support with intraaortic balloon counterpulsation or an LV and/or RV assist device (LAVD or RVAD) may become necessary. Residual effects of cardioplegia, a ventricular aneurysm, or pericarditis may cause ST-segment elevation without actual ischemia.

Off-Pump Coronary Artery Bypass Surgery, Minimally Invasive Coronary Artery Bypass Surgery, and Hybrid Coronary Revascularization

Off-Pump Coronary Artery Bypass Surgery. Awareness of the deleterious effects of CPB has driven advocacy for alternative myocardial revascularization techniques, particularly OPCAB surgery. Proponents of OPCAB cite the low morbidity and mortality of patients who undergo this procedure, as well as faster recovery and reduced procedural costs. Data from the STS suggest that approximately 22% of coronary revascularization procedures are being performed off pump.[331]

The midline sternotomy is the traditional approach used for OPCAB procedures. Potential sources of bypass grafts include the right and left mammary arteries, the saphenous veins, and the radial arteries. The pericardium is incised, reflected, and secured to the edges of the mediastinum. Special sternal retractors allow the placement of adjustable and flexible fixation devices that work by direct surface pressure on the myocardium, by suction, or by both methods. These devices stabilize the target vessel and allow the surgeon to "verticalize" the cardiac apex out of the pericardial well to access the posteriorly and laterally located vessels (Fig. 54.23). Dosing of heparin for OPCAB cases is institution specific; both full-dose and low-dose regimens are currently in use.

When the target vessel and surrounding myocardium are stabilized, an elastic ligature is placed circumferentially around the coronary artery to minimize bleeding as an arteriotomy is performed. Surgical visualization is also optimized by the application of a blower or mister, held by a surgical assistant, that releases sterile irrigation fluid aerosolized in carbon dioxide gas. Under these conditions, one or more distal coronary anastomoses are performed. The proximal connections of saphenous vein grafts or free arterial conduits are anastomosed directly to the aorta with a side-biting clamp. Alternatively, an indirect proximal connection is made by creating a T-graft (end-to-side anastomosis) to a mammary artery that is still connected to a vascular pedicle on the subclavian artery.

Surgical considerations include (1) obtaining adequate exposure of the anastomosis site, (2) restraining cardiac motion during anastomosis, and (3) preserving myocardium during coronary flow interruption.[332] To achieve the first two goals, the surgeon must use maneuvers that may significantly compromise hemodynamics by several mechanisms, including impairment of biventricular filling, particularly in the thin-walled, easily compressed right ventricle. In addition, altered ventricular filling can result from verticalization of the cardiac ventricular apex (which may kink or partially obstruct venous return) (see Fig. 54.23). Furthermore, myocardial ischemia occurs in native coronary arteries and is exacerbated by temporary elastic suture ligation of a target vessel.[328] Ischemia of distal myocardial segments can occur during anastomosis of bypass grafts, and the degree of functional deterioration depends on the severity of the stenosis and the extent of collateralization.[332]

Therefore, the anesthesiologist must take measures to prevent severe hypotension to minimize the reduction in coronary perfusion caused by these hemodynamic changes and intraoperative myocardial ischemia. Typically, intravascular volume loading (either crystalloid or colloid) and a head-down position of the patient are used, and it is also common to administer a vasoconstrictor drug (either phenylephrine or norepinephrine). When increased mitral insufficiency further exacerbates the hemodynamic changes, repositioning the heart is a simple maneuver that may increase ventricular filling and normalize ventriculoannular geometry.

Monitoring of the patient includes a five-lead ECG and an invasive arterial pressure catheter. PAP and CO measurements or continuous pulse contour CO can be considered.[332] TEE is beneficial, but views are limited during certain portions of the surgical procedure; verticalization of the heart and the application of external compression footplates cause suboptimal imaging. The midesophageal

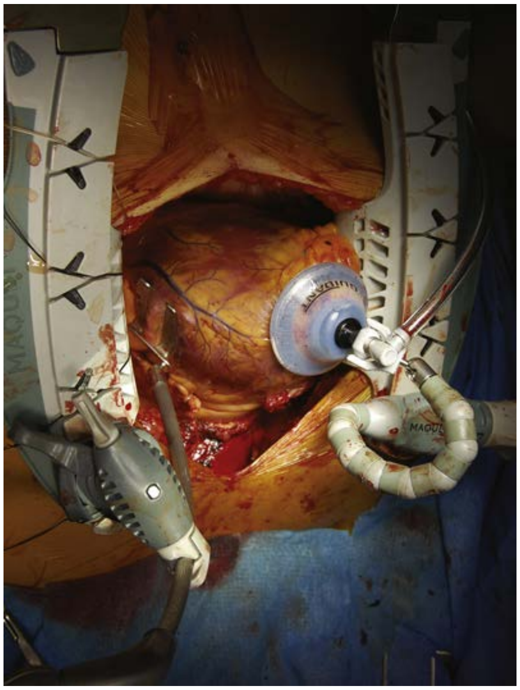

Fig. 54.23 Image depicting the first obtuse marginal (OM1) anastomosis during off-pump coronary artery bypass grafting with a saphenous vein graft. The view is from the head of the patient. The previously completed left internal mammary artery-to-left anterior descending coronary artery anastomosis is seen. The Maquet access device (MAQUET, Wayne, NJ) uses suction to position the heart (verticalization) for easy access to the circumflex coronary artery system. (Courtesy Alexander Mittnacht, MD, Mount Sinai School of Medicine, New York; From Mittnacht AJC, Weiner M, London MJ, et al. Anesthesia for myocardial revascularization. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 6th ed. St. Louis: Saunders; 2011:524.)

imaging view, rather than the transgastric view, may be best for continuous TEE monitoring while distal coronary anastomoses are performed.

Persistent or worsening ECG change or impending cardiovascular collapse warrants quick action on the part of the anesthesiologist and surgeon. One option is to have a low threshold for the insertion of small, flexible intracoronary stents into the open coronary anastomosis to allow some distal segment flow. Instituting full or partial CPB and placing an IABP are other therapeutic options. Emergency conversion from OPCAB to CABG with CPB, which occurs in approximately 3% of these cases,[333,334] is not an innocuous event. Such unplanned conversions are reportedly associated with an elevated risk of death, stroke, renal failure, wound infections, and respiratory failure.

The short-term outcomes and long-term efficacy of OPCAB surgery continue to be investigated and debated in the literature. Meta-analyses have noted no significant differences in 30-day mortality.[335,336] In the largest multicenter randomized trial to compare on-pump CABG with OPCAB, no difference was seen in 30-day mortality or the composite outcome of death and complications.[337] In contrast, very large observational analyses do suggest a mortality benefit. Hannan and associates found a mortality benefit in 49,830 patients from the New York State registry by using a risk-adjusted analysis (i.e., Cox proportional hazard models and propensity analysis).[338] However, the need for repeat revascularization was greater among OPCAB patients (93.6%) than CABG patients (89.9%).[338] Several large retrospective reviews of traditional CABG versus OPCAB procedures have found a gender-specific survival benefit for women who undergo OPCAB surgery, compared with those who undergo on-pump CABG.[339-341]

A recent 5-year trial of more than 4000 patients from 19 different countries found no difference in stroke, MI, renal failure, repeat revascularization, and death at 5 years of follow up of patients who underwent on-pump versus off-pump CABG.[342]

Minimally Invasive Coronary Artery Bypass Surgery. The most popular alternative approach to sternotomy is the minimally invasive coronary artery bypass (MIDCAB) through a left anterior thoracotomy, which allows direct-access IMA harvesting and grafting to the LAD artery. Some surgeons harvest the left IMA (LIMA) by using robot-assisted endoscopic technology before making the small incision to complete the LIMA-to-LAD anastomosis through the left anterior thoracotomy incision. In these cases, deflation of the left lung is required for visualization of the anastomosis, accomplished with a double-lumen endotracheal tube or a bronchial blocker. In addition, carbon dioxide is insufflated into the left hemithorax during the period while the lung is deflated.

Usually, the MIDCAB technique involves grafting of only a single vessel, and exposure for this anastomosis may be suboptimal.[332] Challenges for the anesthesiologist in MIDCAB cases include the need for single-lung ventilation while the LIMA is dissected, and the anastomosis is performed. Because the graft is only to the LAD in these cases, no extreme positioning of the heart occurs that could significantly compromise hemodynamic status. However, external defibrillator or pacing pads should be attached to the patient before preparing and draping because surgical access to the heart is limited during these procedures.[343]

Since the MIDCAB procedures were first introduced, as the technology has evolved so have the surgical techniques and the anesthetic techniques. Still, there are a variety of different ways to manage anesthetics for MIDCAB operations and different institutions have different techniques that they employ to take care of these patients.

In addition to standard ASA monitors, these patients are monitored with an arterial line (preferably in the radial artery), a central line introducer, and potentially a PA catheter.

Patients presenting for MIDCABs are induced in a routine fashion, as for any patient undergoing CABG surgery. In order to maximize surgical exposure by lung isolation, cardiac anesthesiologists prefer to intubate with double lumen endotracheal tubes or use bronchial blockers for MIDCAB surgeries.[344] Maintenance of anesthesia must keep in mind that the MIDCAB is an off-pump case. Hemodynamic control is achieved by fluid administration and pharmacology. Norepinephrine and phenylephrine have both been used effectively for these cases. Procedures for extubation after MIDCAB vary from institution to institution.

Outcomes of MIDCAB. Multiple studies over the years have evaluated the outcomes of MIDCAB, both in the United

States and abroad. MIDCAB has shown promise when compared to the conventional CABG surgery. MIDCAB is associated with less morbidity and mortality when compared to on-pump and off-pump CABG procedures.[345,346]

TOTAL ENDOSCOPIC CORONARY ARTERY BYPASS. Total endoscopic coronary artery bypass (TECAB) is currently the most minimally invasive approach to performing CABG. TECAB is performed via a few port sites (Fig. 54.24),[347] with the surgeon remotely controlling the ports via a robotic system.[347]

TECAB is performed in three different ways: arrested heart TECAB, beating heart TECAB with CPB, and beating heart TECAB without CPB. Defibrillation pads are placed on the patient in the preoperative period. In cases where the heart is arrested, a remotely accessed perfusion technique is used with the help of an endoaortic occlusion balloon clamp (EAOBC) (Fig. 54.25).[347]

The EAOBC is placed via the femoral vessels, or via the axillary artery if accessing the femoral vessels or the descending aorta is contraindicated or not possible. TEE can provide useful information to guide placement of the EAOBC.

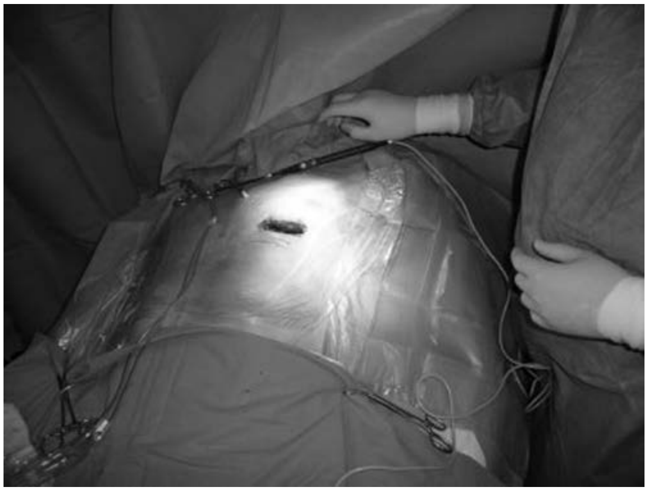

Fig. 54.24 TECAB is performed via a few port sites, with the surgeon remotely controlling the ports via a robotic system.

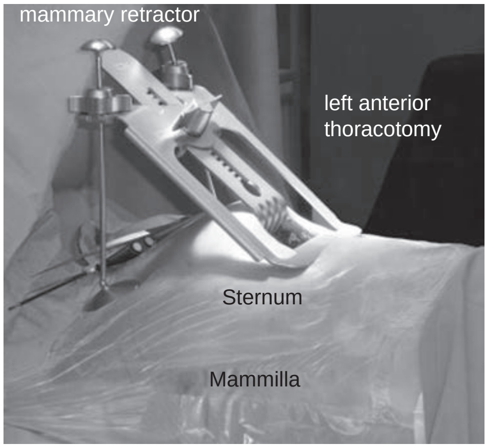

Fig. 54.25 Remotely accessed perfusion technique with an endoaortic occlusion balloon clamp (EAOBC).

ANESTHETIC CONSIDERATIONS. Anesthetic management of patients undergoing TECAB differs from general anesthesia for routine cardiac cases. General anesthesia is induced in routine fashion. Since one lung ventilation is needed for these procedures, this goal is achieved by either using a double lumen endotracheal tube, or a bronchial blocker, similar to the MIDCAB. At least one large-bore peripheral intravenous line, a central line with an introducer, and bilateral radial arterial lines are required for TECAB procedures. Bilateral radial arterial lines are used to monitor the position of the EAOBC to ensure that it doesn't migrate and occlude the innominate artery. TECAB cases may require placement of a PA vent or a coronary sinus catheter. Supplemental regional anesthesia has been reported to have been successfully employed in TECAB cases, which can facilitate early extubation in these patients.[347] Extubation of TECAB patients is mostly dictated by patients' comorbidities.

TEE IN TECAB. TEE serves as a crucial tool in the management of patients undergoing minimally invasive procedures. In addition to the usual monitoring and diagnostic capabilities of TEE, it is also used to monitor major vascular structures and to guide cannulas and catheters during the cannulation process.

In cases where the EAOBC is used, TEE provides real-time imaging of the position of the balloon, which serves as a critical monitor for migration or malposition.

OUTCOMES OF TECAB. Similar to MIDCAB there is a paucity of large-scale randomized studies looking at the outcome data for TECAB procedures. Studies looking at smaller number of patients are promising, though acknowledge their limitations.[348]

Hybrid Coronary Revascularization. Hybrid coronary revascularization combines MIDCAB techniques with catheter-based interventions.[349] Ideally, a hybrid operating room is used. The surgical component of the hybrid procedure may be offered in a completely endoscopic fashion, using robotic technology. The goal of such procedures is a very short recovery time.[349] Although the perioperative results and intermediate-term outcomes of hybrid procedures appear to meet the standards of CABG performed with CPB, no data on long-term outcomes are available.

Patients undergoing OPCAB, MIDCAB, or hybrid coronary revascularization do not undergo CPB, and thus may suffer from temperature alterations that cannot be treated using the CPB perfusate temperature. Therefore, heating blankets for patients and a warm operating room environment are essential to prevent unacceptable reductions in body temperature.

ANESTHETIC MANAGEMENT OF HYBRID CORONARY REVASCULARIZATION. As mentioned earlier, HCAR combines coronary revascularization via a minimally invasive surgical approach and catheter-based coronary intervention. HCAR can be done in a staged manner.

A two-stage model used commonly in the early days of the procedure requires the patient to have either surgery or PCI and then return at a later date for the other part of the procedure. This entails two separate admissions, two separate procedures, along with the concomitant patient and family inconvenience. Anesthesiologists are involved in the surgical procedures in a hybrid revascularization, though they are rarely involved in the PCI. The one-stage model allows for both the surgical and the PCI revascularization to be done in one admission, typically in one sitting in a hybrid operating room. Patients can be exposed to one anesthetic and can undergo the surgical procedure and the PCI sequentially, in either order.

HYBRID CORONARY REVASCULARIZATION OUTCOMES. Though large-scale studies are lacking at this time, smaller institutional-based studies looking at outcomes are increasing, thus adding to the body of literature in this regard. A review of the available data suggests that HCAR outcomes are promising, which is not surprising since HCAR takes advantage of the benefits of CABG and PCI while minimizing the risks of each. If outcomes are similar or superior to those of conventional revascularization, then a careful cost-benefit analysis will take place to determine the role that HCAR holds in our armamentarium.[350]

CARDIAC VALVE LESIONS

Mitral Valve Disease

In the United States and other industrialized nations, mitral valve disease is usually caused by primary degenerative (i.e., age-associated) or inherited mitral valvular abnormalities or, increasingly, by ischemic heart disease resulting in functional mitral incompetence. In developing countries, conversely, rheumatic heart disease is relatively more prevalent and therefore a more common cause of mitral valve disease.[351] Primary or “organic” mitral valve disease involves abnormalities in the valve itself or in its subvalvular structural components.[352] Mitral valve prolapse, myxomatous degeneration of the mitral valve, rheumatic mitral insufficiency, cleft mitral valve associated with an AV septal defect, and any infiltrative or fibrotic processes caused by systemic diseases are all associated with inherent structural abnormalities of the mitral valve.

Anatomy of the Mitral Valve

Mitral valve anatomy includes the leaflets, commissures, chordae, annulus, papillary muscles, and the LV. The mitral valve has two leaflets, the anterior mitral leaflet (AML) and the posterior mitral leaflet (PML). Both leaflets are subdivided according to the Carpentier classification. The PML is divided into three scallops: the anterior or medial scallop (P1), the middle scallop (P2), and the posterior or lateral scallop (P3). The corresponding AML sections that oppose these PML scallops are similarly called A1, A2, and A3 (Figs. 54.26 and 54.27). The AML is broad in shape, occupies a larger portion of the mitral valve area (MVA) than the PML, yet attaches itself to only twofifths of the annulus. The PML, though smaller in area, is crescentic in shape and attaches to threefifths of the annulus. Fig. 54.28[353] shows the components of the mitral valve leaflets using three-dimensional echocardiography. Common nomenclature is used to ensure accurate communication between the surgeon and the echocardiographer.

The commissures of the mitral valve define the area where the leaflets come together at their annular insertion sites. Chordae tendineae originate from the papillary muscle heads and attach to the mitral leaflets. Chordae are generally divided into three types. Primary chordae attach to the free margins of the leaflets, thus preventing the prolapse of the margins and ensuring alignment of the “rough edges” for coaptation. Secondary chordae attach to the body or the ventricular surfaces of the two leaflets and prevent billowing during systole, additionally providing a reduction in tension. Tertiary or basal chordae extend from the papillary muscle to the annulus of the valve.

The mitral annulus is the anatomical junction between the LA and the LV and attaches to the mitral valve leaflets in an anterior and a posterior segment. The anterior segment also provides the attachment to the fibrous trigones. There are two fibrous trigones, the right and the left. Parts of the mitral, tricuspid, aortic annuli, and the membranous portion of the interventricular septum comprise the right fibrous trigone. The fibrous left border of the aortic-mitral curtain makes up the left fibrous trigone. The fibrous skeleton of the heart is not continuous in the region of the posterior mitral annulus, thus this area is relatively weaker and prone to enlarge with the dilatation of the left heart. The overall shape of the mitral annulus is saddle-like, and during systole, the mitral annulus contracts as the commissures move toward the apex.

The anterolateral and the posteromedial papillary muscles attach to the LV free wall between the middle third and the apex of the ventricle. The anterolateral papillary muscle has one body (or head) while the posteromedial muscle can have two or more bodies. Blood supply to the anterolateral muscle can originate from one or more branches of the left coronary artery, while the posteromedial papillary muscle only has a single blood supply (i.e., from the circumflex coronary artery). This explains the vulnerability of the posteromedial papillary muscle to ischemia and infarction. Due to the intricate connections of the papillary muscles to the LV, changes in ventricular geometry can cause distortion and abnormal functioning of the mitral valve.[354]

Mitral Stenosis

PATHOPHYSIOLOGY. The disease process of rheumatic mitral stenosis (MS) includes thickening, commissural fusion, and increased rigidity of the mitral valve leaflets, as well as thickening, fusion, and contracture of the

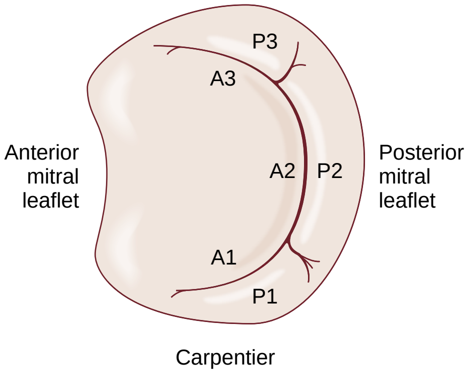

Fig. 54.26 Standard terminology as applied to the mitral valve leaflets is illustrated in this image. The anterior and posterior mitral valve leaflets are each divided into three segmental regions. chordae and papillary heads. Furthermore, with longstanding rheumatic disease, some degree of calcification of the valve apparatus inevitably occurs. Physiologically, these changes result in obstruction at the level of the mitral valve.

The normal mitral valve orifice area is approximately 4 to 5 cm^2.[355] Symptoms can occur if the valve area is less than 2.5 cm^2 and can be precipitated by clinical events associated with increased CO and consequent increased flow across the valve; these events include stress, exercise, anemia, pregnancy, and febrile illness (Fig. 54.29). Symptoms do not usually occur at rest unless the MVA is less than 1.5 cm^2. Obstructed flow across the mitral valve is associated with a pressure differential or gradient across the valve. The more severe the MS, the greater the gradient, as long as flow across the valve is held constant. Grading of MS is shown in Table 54.14.[353]

Transmitral pressure gradients through the mitral valve depend on the volume flow rate. Severe MS may be present with a low measured or calculated gradient across the valve, as in patients with right HF and pulmonary hypertension. An MVA estimate is a more independent measure of the severity of MS. Currently, MS is primarily diagnosed and monitored with echocardiography, although MVA can be calculated during catheterization by using the Gorlin equation.[356] Assessing MS severity by echocardiography involves two-dimensional planimetry of the valve orifice and Doppler-derived measurements of gradient, pressure half-time, and deceleration time. The advent of three-dimensional technology has enabled clinicians to visualize the mitral valve anatomy more accurately (Fig. 54.30).[354]

Management considerations in MS emphasize the pathophysiologic changes that occur in the left atrium, the pulmonary vasculature, the right heart, and the LV. Obstructed mitral inflow with secondary increases in LA pressure (LAP) gradually causes enlargement of the left atrium, which can lead to the onset of atrial fibrillation, thromboembolic complications, or both if low blood flow velocity causes clot formation in the atrium or appendage.

Patients with MS and chronic atrial fibrillation are at increased risk of embolic stroke, at a rate of 7% to 15% per year.[356] Treatment may include anticoagulation with intravenous heparin or oral warfarin, pharmacologic rate control, and pharmacologic or electrical cardioversion for hemodynamically significant or acute-onset atrial fibrillation. In patients scheduled for cardioversion, TEE may need to be performed first to rule out the presence of LA thrombus.[355]

Elevated LAP leads to passive increases in pulmonary venous and arterial pressures. Most patients with MS have a greater PAP than would be expected if PAP were estimated solely from elevations in LAP. These exaggerated pressures are secondary to reactive pulmonary vasoconstriction or histologic changes in the medial and intimal layers of pulmonary arteries and arterioles. PAP sometimes correlates with the severity of MS, but pressures can range widely because of factors such as transmitral pressure gradient, LVEDP, the actual MVA, and a history of chronic pulmonary disease.

The chronic elevation in PAP caused by MS leads to compensatory and decompensatory changes in the right ventricle. Exposure to elevated pressure leads to compensatory RV hypertrophy; however, the response in the right ventricle is less efficient than in the LV because of the shape, wall thickness, and smaller muscle mass of the right ventricle. Because of the right ventricle's relative vulnerability, chronic pulmonary hypertension invariably leads to progressive RV dilation and eventual RV failure.

The effect of MS on the LV is primarily the result of obstruction of diastolic inflow. The narrowed mitral valve orifice leads to prolonged early diastolic mitral inflow and delayed filling of the LV. Late diastolic filling, which occurs during atrial systole, is obviously compromised in patients who have atrial fibrillation secondary to MS. In cases of MS, pressure-volume loops are shifted to the left, so LVEDP and LV end-diastolic volume (LVEDV) are lower. Stroke volume is diminished, especially in clinical situations that result in elevated heart rate and shortened diastolic filling intervals (Fig. 54.31).[357]

LV function or contractility is assumed to be normal in most patients with MS. However, in a review of the literature,

TABLE 54.14 Grading of Mitral Stenosis

Severity	MVA, cm^2	Gradient, mm Hg	PAP	Symptoms	Signs	Therapy
Mild	>1.8	2-4	Normal	Usually absent	S_2-OS >120 ms; normal P_2	IE prophylaxis
Moderate	1.2-1.6	4-9	Normal	Class II	S_2-OS 100-120 ms; normal P_2	IE prophylaxis; diuretics
Moderate to severe	1.0-1.2	10-15	Mild pulmonary HTN	Class II–III	S_2-OS 80-100 ms; P_2 increase	IE prophylaxis; BMV if applicable or surgery if more than mild Sx
Severe	<1.0	>15	Mild to severe pulmonary HTN	Class II–IV	S_2-OS <80 ms; P_2 increase; RV lift Sx if R heart fails	IE prophylaxis; BMV or surgery

Klein and Carroll showed that the assumption of preserved LV contractility in patients with MS is debatable.[358] Instead, the prevalence of LV dysfunction in patients with MS may be as high as 30%. Proposed mechanisms include reduced filling of the LV, muscle atrophy, inflammatory myocardial fibrosis leading to wall-motion abnormalities, scarring of the subvalvular apparatus, abnormal patterns of LV contraction, reduced LV compliance with diastolic dysfunction, increased LV afterload leading to ventricular remodeling, right-to-left septal shift secondary to the effect of pulmonary hypertension on the right ventricle, and coexistent diseases such as systemic hypertension and CAD.[358] The hemodynamic changes associated with MS are summarized in Fig. 54.29.

Anesthetic Management. An understanding and appreciation of the pathophysiologic changes associated with MS form the foundation of anesthetic management in these patients (Table 54.15). Primary concerns in patients with MS include managing ventricular preload, heart rate, and coexisting pulmonary hypertension, as well as potentially diminished RV and LV contractile function. Most patients with valvular heart disease have increased dependency on and sensitivity to ventricular preload. Flow through a stenotic mitral valve requires a higher-than-normal pressure gradient between the left atrium and the LV. Thus, reduction in preload, either from blood loss or from the venodilatory effects of anesthesia, can markedly affect stroke volume, CO, and tissue perfusion. However, in higher grades of MS, LAP may be very high, and the difference between adequate filling pressure and an LAP that leads to congestive failure may be small. Thus, judicious fluid management is required.

In patients with MS, the heart rate should be kept within its normal range. Tachycardia may be poorly tolerated because of the decreased time for diastolic filling. Moreover, pressure gradients are somewhat flow dependent in MS. Elevated flow states, such as pregnancy and increased sympathetic activity from any source, can dramatically increase the pressure gradient across the valve and are reflected in elevated LAP or pulmonary venous pressure. From data obtained by continuous wave Doppler interrogation of the inflow velocities across the mitral valve, the pressure gradient is derived through the use of a modified form of Bernoulli's equation, $\Delta P = 4v^2$, where v is the measured velocity of blood flow through the valve. Thus, any increase in transvalvular flow rate caused by an increase in heart

rate has a significant impact on transvalvular flow dynamics and on LAP.

Atrial contributions to stroke volume may be elevated in patients with MS who are in the early stages of the disease and are not in atrial fibrillation. When atrial fibrillation has occurred, the atrial kick is lost. However, the most important factor in the deterioration of the patient's clinical condition is tachycardia itself, rather than loss of the atrial kick.

Contractility and SVR are usually preserved in MS. If anything, the LV is chronically underloaded, but wall motion abnormalities or global systolic dysfunction develop in a small percentage of MS patients. Usually, SVR is not a factor in augmenting forward flow because stroke volume is determined by the mitral valve orifice area and the diastolic filling interval. It may be appropriate to lower SVR for an LV that has marked systolic dysfunction, but care must be exercised because a reduction in afterload is inevitably accompanied by a reduction in preload, which may not be desirable in patients with significant MS.

RV dysfunction probably poses a greater challenge in treating patients with MS than does LV dysfunction. The chronic elevations in LAP can be persistent in patients with long-standing pulmonary hypertension. In the patient with residual pulmonary vascular disease and irreversible pulmonary hypertension, supporting a failing or marginally functional right ventricle becomes the top clinical priority.

Monitoring includes standard noninvasive modalities and invasive monitoring of blood pressure, CVP, and intraoperative echocardiography. Monitoring PAP and using a PA catheter to monitor CO may be very helpful, but care and judgment must be exercised, given the propensity for PA rupture in patients with long-standing pulmonary hypertension. Inotropic support may be needed for patients with secondary RV dysfunction or failure. Epinephrine and milrinone are good therapeutic options. Management of RV dysfunction includes optimizing acid-base balance and using hypocapnia, hyperoxia, and possibly vasodilators to decrease PVR.

Mitral Regurgitation. The complex anatomic structure of the mitral valve is especially pertinent in any consideration of the pathophysiology and management of patients who present for operative intervention for MR. The mitral apparatus consists of six primary components: the LA wall, the annulus of the mitral valve, the mitral valve leaflets, the chordae tendineae, the papillary muscles, and the wall of the LV. Abnormalities or dysfunction in any component can result in mitral valve incompetence.

MR can be classified as either organic (intrinsic valvular disease) or functional (i.e., related to nonvalvular components of the mitral apparatus).[359] It is common for MR to have a functional and an organic component, as in rheumatic valve disease resulting in annular or LV dilation with superimposed abnormalities of leaflet coaptation. In developed countries, the most common causes of MR are as follows: (1) myxomatous degeneration of the mitral valve resulting in annular dilation, chordal elongation and rupture, and redundant, prolapsing, or flail mitral valve leaflets; and (2) mitral insufficiency caused by ischemic heart disease. The most common indication for surgical repair or replacement of the regurgitant mitral valve is myxomatous degeneration, which includes mitral valve prolapse syndromes.[360] Chronic ischemic or functional MR is present in 10% to 20% of patients with CAD and, unlike MR with primary valvular causes, it does not involve abnormalities in the morphology of the mitral valve.[361] Nonetheless, the long-term morbidity and mortality associated with this type of MR are significant.[352]

The severity of MR is assessed in the context of whether the MR is acute or chronic. Symptom presentation, physical examination, hemodynamics, and echocardiography all provide useful information for ascribing a severity grade (Table 54.16). Echocardiographic assessment is particularly important for guiding intraoperative decisions about the need for intervention and the adequacy of repair or replacement of the mitral valve (Fig. 54.32). As with MS, several echocardiographic parameters, both two-dimensional and Doppler-derived, can be used to grade the severity of MR (Table 54.17). The advent of three-dimensional technology

MR, Mitral regurgitation.

From Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the 1998 guidelines for the management of patients with valvular heart disease). Endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol*. 2008;52:e1–142.

and current calculation software greatly improved clinicians' ability to assess the severity and identify the precise cause of MR (Fig. 54.33; see also Fig. 54.32).

Pathophysiology. The incompetent mitral valve allows retrograde passage of blood from the LV into the left atrium during systole. The magnitude of the regurgitant volume is a function of the size of the regurgitant orifice, the pressure differential between the left atrium and the LV, and the duration of the regurgitant cycle.[359] Thus, higher systolic driving pressures, as in hypertension, can increase the regurgitant volume. Loading conditions are important as well, especially whenever functional changes in annular and LV geometry are important components of the mechanism of MR. These conditions should be considered during the intraoperative evaluation of MR because anesthetic effects on afterload and preload can drastically alter the severity of MR from its baseline level, as seen in preoperative echocardiographic or catheterization assessments. (Table 54.18)

LV function and pressure tend to be normal in patients with chronic MR. EF is often normal or supranormal unless the ventricle has decompensated with chronic MR or is acutely ischemic. A normal EF can be misleading, and masked ventricular dysfunction may be revealed after valve repair or replacement. The left atrium serves as a low-pressure pathway during systolic ejection, so that EF overestimates ventricular function.

When MR has an acute onset, LAP is elevated, because LA compensatory changes have had no time to occur. A v-wave may be present on the LAP, PAP, or PCWP recordings. In contrast, in chronic MR, the LAP increases are less dramatic because of compliance changes in the left atrium as a function of chamber dilation.

The long-term sequelae of MR are related to chronic pressure and volume effects on the left atrium and the LV. The LV is exposed to a chronic, isolated volume-overload state. Eccentric hypertrophy of the LV develops, causing chamber enlargement without significant increases

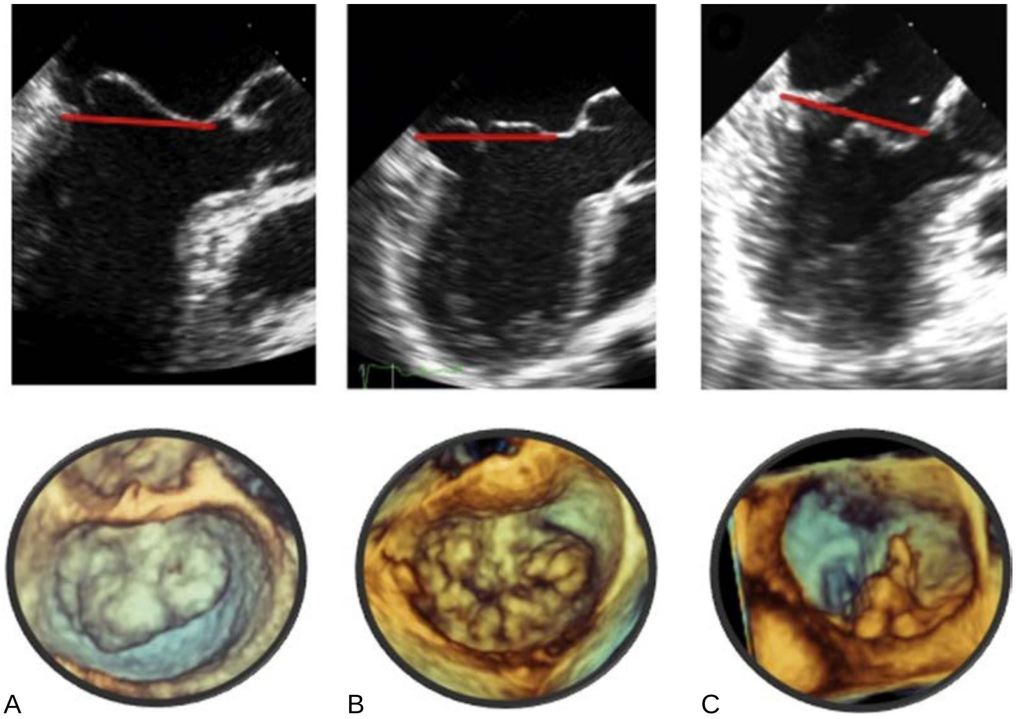

Fig. 54.33 Differential diagnosis of mitral leaflet prolapse. Two-dimensional (2D) transesophageal echocardiography (TEE) long-axis view demonstrating anterior leaflet prolapse (A, *top*) with a three-dimensional (3D) transesophageal example as seen from the left atrium (A, *bottom*). Leaflet prolapse should be diagnosed when the free edge of the leaflet overrides the plane of the mitral annulus during systole. 2D TEE long-axis view demonstrating bileaflet billowing of the mitral valve with prolapse resulting from chordae tendineae elongation (B, *top*) with a 3D transesophageal example as seen from the left atrium (B, *bottom*). Leaflet billowing is diagnosed when systolic excursion of the leaflet body occurs into the left atrium resulting from excess leaflet tissue, with the leaflet free edge remaining below the plane of the mitral annulus. 2D TEE long-axis view demonstrating flail valve resulting from chordae rupture (C, *top*) with a 3D transesophageal example of P2 flail as viewed from the left atrium (C, *bottom*). (From Lang RM, Tsang W, Weinert L, et al. Valvular heart disease: the value of 3-dimensional echocardiography. *J Am Coll Cardiol.* 2011;58:1933–1944.)

TABLE 54.18 Pathophysiologic Changes Associated With Mitral Regurgitation

	LV Preload	Heart Rate	Contractility	Systemic Vascular Resistance	Pulmonary Vascular Resistance
Mitral regurgitation	↑ or ↓	↑, maintain	Maintain	↓	↓

LV, Left ventricular.

From Townsley MM, Martin DE. Anesthetic management for the surgical treatment of valvular heart disease. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:346.

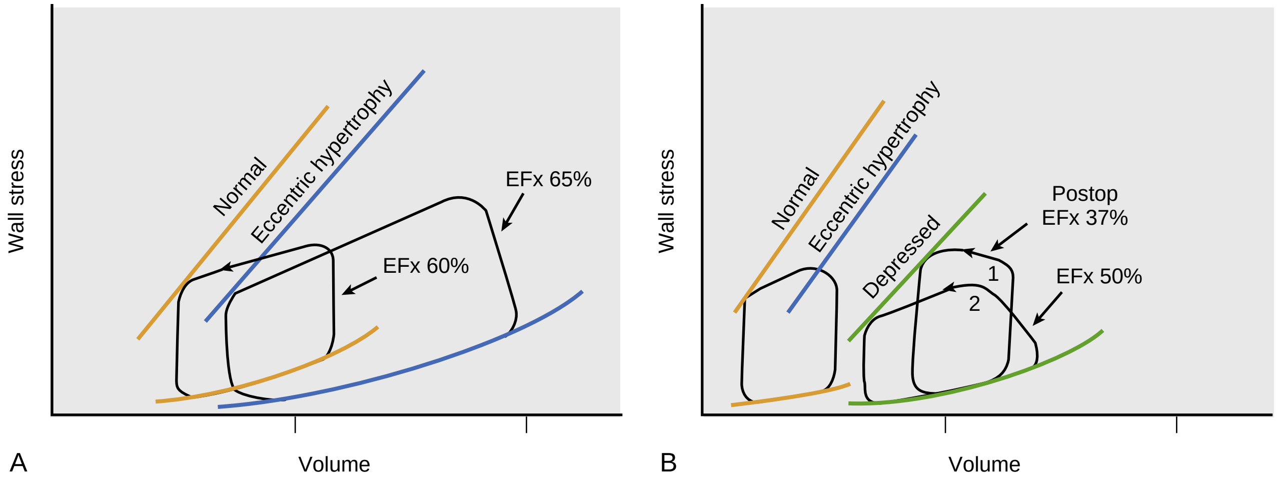

Fig. 54.34 Diagram of wall stress–volume loops and end-systolic volume–wall stress relationships in severe mitral regurgitation. (A) As in aortic regurgitation, the shift to the right of the diastolic and end-systolic relationships allows the volume-overloaded left ventricle to maintain a high stroke volume. Mean wall stress during ejection is somewhat reduced, and in mitral regurgitation the ejection fraction (EFx) is high normal when contractility is normal. (B) With the development of depressed contractility, the end-systolic wall stress–volume relationship is shifted to the right preoperatively. Despite severely depressed contractility, the ventricle is able to deliver a nearly normal EFx because of the very large ventricular volume and the relatively low mean wall stress during ejection (beat 2, EFx = 50%). Contractility remains depressed after mitral valve replacement (Postop), and with correction of the low-impedance leak, the ventricle must now deliver the total stroke volume into the aorta against higher wall stress; the EFx therefore falls to 37% (beat 1).

in wall thickness. Forward CO is preserved because of eccentric hypertrophy and the low impedance of the left atrium—a physiologic equivalent of afterload reduction. The larger stroke volume ejected by the LV is composed of the normal venous return into the left atrium in addition to the regurgitant volume from the previous cardiac cycle. In the early stages of MR, LVEDP is relatively normal because of compliance changes of the LV. With time, however, compensatory eccentric hypertrophy fails to preserve LV systolic function, and gradual systolic failure ensues, as noted on pressure-volume loops (Fig. 54.34). In patients with MR, deciding on the timing of surgical intervention is an important duty of the referring cardiologist because LV systolic performance can deteriorate to a point that full functional recovery after valve surgery may not be possible.

The LA is exposed to increases in volume and pressure. The LA dilates to compensate for the regurgitant volume during systole, and in the early stages of MR, preservation of near-normal LAP and protection of the pulmonary vasculature is likely. Progressive LA enlargement commonly leads to atrial fibrillation, which occurs in approximately 50% of patients who are about to undergo surgical correction of MR. However, patients with MR appear to be at a lower risk for thromboembolic complications than are patients with MS.

When LAP compliance thresholds are reached, LAP and PAP become elevated. Eventually, if chronically exposed to elevated PAP, the right ventricle progressively enlarges, and RV dysfunction develops.

Carpentier classifies MR into three different types by the mechanism causing regurgitation. Type I MR is characterized by "normal leaflet motion" and annular dilatation as the cause of regurgitation. Type II MR is caused by excessive motion of the margin of a leaflet and is the most common of the three etiologies. In the type II etiology excessive motion causes the leaflet to rise above the annular plane. Type III MR is characterized by restricted motion of the mitral leaflet. It is further subdivided into two components: Type IIIa is due to fibrosis of the subvalvular apparatus of the mitral valve, whereas IIIb is due to tethering of the leaflet to the ventricular wall as a result of remodeling of the ventricle (ischemic etiology).[354]

Fig. 54.27[354] shows the above mentioned Carpentier classification.

Anesthetic Management. In the anesthetic management of MR, the primary goal is maintaining forward systemic flow. In chronic, compensated MR, maintaining preload, judiciously reducing afterload, and keeping the heart rate in the high-normal range may be adequate (see Table 54.18).

As with most compensated forms of valvular heart disease, patients with hemodynamically significant MR are sensitive to ventricular loading conditions. Augmenting preload may be prudent in the interval before anesthetic induction. However, MR is dynamic; ventricular distention can lead to the expansion of an already dilated mitral annulus and thus worsen MR.

The heart rate should be maintained in the high-normal range (i.e., 80-100 beats/min). Bradycardia has dual detrimental effects on MR: it lengthens the systolic period, thus prolonging regurgitation, and it increases the diastolic filling interval, which can lead to LV distention. A sinus rhythm is preferred, but with less dependency on the atrial kick in chronic, compensated MR than in stenotic valvular heart disease.

LV contractility may be preserved in early compensated MR. However, EF indices are poorly correlated with LV systolic function in patients with moderate to severe MR, and underlying systolic dysfunction may be woefully underestimated. Hypotension in patients with significant MR can be managed to a certain degree by manipulating heart rate and volume, but persistent hemodynamic instability may be best treated with inotropic support. Dobutamine,

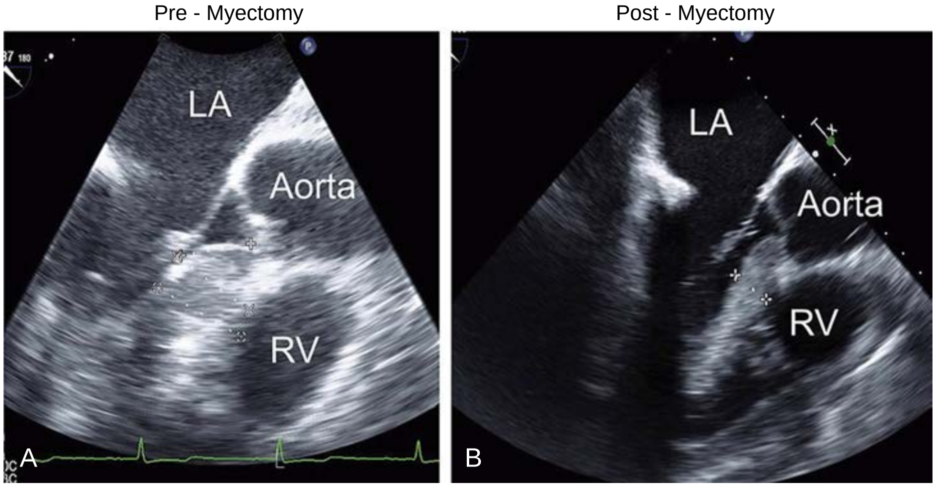

Fig. 54.35 Transesophageal echocardiography of septal measurements before myectomy (A) (thickness, 2.9 cm) and after myectomy (B) (thickness, 1.5 cm). *LA*, Left atrium; *RV*, right ventricle. (From Nagueh SF, Bierig SM, Budoff MJ, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with hypertrophic cardiomyopathy: endorsed by the American Society of Nuclear Cardiology, Society for Cardiovascular Magnetic Resonance, and Society of Cardiovascular Computed Tomography. *J Am Soc Echocardiogr*. 2011;24:473–498.)

low-dose epinephrine, and milrinone are all acceptable inotropic choices, depending on the clinician's interpretation of the monitor data.

With respect to SVR, the general rule of thumb for patients with MR is to decrease afterload so that forward CO is maximized. Adequate anesthetic depth, systemic vasodilators, inodilators, and at times mechanical reduction of afterload with an IABP may be clinical options, depending on the situation. Direct-acting α_1-agonists increase SVR and blood pressure, lower heart rate, and may worsen the MR. Temporary use of small doses of ephedrine may be a better choice, after which inotropic support should be considered if a persistent need exists to augment pressure.

Both PAP and PVR may be elevated in patients with either acute or long-standing MR. Secondary changes in RV size and function may be important clinical considerations. Factors that may increase PVR and unfavorably load an already dysfunctional right ventricle (e.g., hypoxia, hypercarbia, and acidosis) should be remedied whenever possible.

Finally, in the patient with acute, severe MR and cardiogenic shock from ischemic rupture of a papillary muscle, pharmacologic support of the LV, often accompanied by mechanical support with IABP counterpulsation, may be necessary.

Hypertrophic Obstructive Cardiomyopathy and the Mitral Valve. Hypertrophic obstructive cardiomyopathy (HOCM) may result in dynamic valvular insufficiency, as well as LV outflow tract (LVOT) obstruction. In addition, surgical attempts to repair an incompetent mitral valve can create iatrogenic LVOT obstruction.

Classically, HOCM is a familial disease transmitted with autosomal dominant inheritance. Inheritance and phenotypic expressions are heterogeneous and vary in their manifestations. Some mutations in genes that code for cardiac sarcomere proteins can cause hypertrophy of segments of the ventricle. Septal involvement is common, but HOCM can involve other areas of the LV as well.[362] This disease is the most common cause of sudden death in young people, but it can also cause death and morbidity in older patients.

When the basal septum of the LV is affected, the LVOT can narrow (Fig. 54.35). Depending on the shape of the ventricle and the mitral valve, dynamic outflow tract obstruction can occur, paired with mitral valve insufficiency. As the outflow tract is narrowed by hypertrophy, the basal septum and the anterior leaflet of the mitral valve come into close proximity. The hypertrophy and the reduced septal–anterior leaflet distance can create a channel that narrows to the point of creating a pressure gradient across the outflow tract. This obstructed flow and its pressure gradient lead to progressive compensatory hypertrophy that, in turn, further narrows the outflow tract and worsens the gradient. As blood is ejected through this narrowed outflow channel during systole, the velocity of blood through the narrowed orifice increases. This increased blood velocity creates a Venturi effect that pulls the anterior leaflet of the mitral valve or the chordal structures into the outflow tract, thus leading to mechanical and dynamic obstruction of the LVOT and also causing MR because of a coaptation defect of the mitral valve.[363] Echocardiographically, this is termed systolic anterior motion (SAM) of the mitral valve (Fig. 54.36). Such dysfunctional mitral valve motion is seen in cardiac surgical patients who present for surgical management of known HOCM (i.e., for surgical myomectomy, mitral valve repair, or both).

Sometimes, SAM is noted preoperatively or as an incidental finding at the time of surgery in patients who present for surgical revascularization or mitral valve repair. Furthermore, SAM may be created iatrogenically as a result of surgical mitral valve repair. In patients with MR who are to undergo mitral valve repair, echocardiographic assessment and surgical inspection are performed to elucidate the mechanism of the mitral insufficiency. The patient may have ruptured or elongated chordal attachments, redundant or prolapsing leaflet tissue, or annular dilation that reduces effective leaflet coaptation. Frequently, multiple contributing factors are present. Surgical treatment can involve just a simple annuloplasty ring in the case of isolated annular dilation, but it more commonly involves resection of diseased segments of the mitral valve, possibly chordal reassignment or reconstruction, and a ring valvuloplasty.

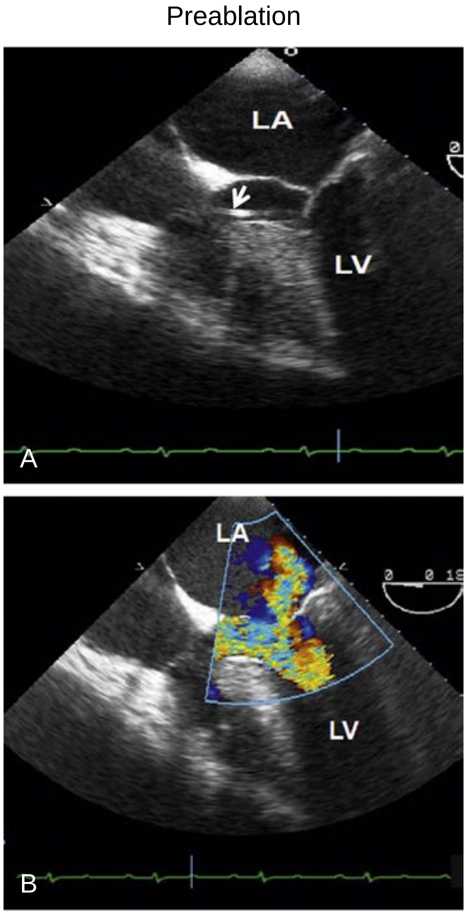

Fig. 54.36 Transesophageal echocardiographic images. (A) Two-dimensional image shows a narrowed left ventricular outflow tract with systolic anterior motion *(arrow)*. (B) Color Doppler image shows high-velocity signals in mosaic color; eccentric mitral regurgitation is directed posterolaterally. *LA,* Left atrium; *LV,* left ventricle. (From Naguch SF, Bierig M, Budoff MJ, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with hypertrophic cardiomyopathy. *J Am Soc Echocardiogr.* 2011;24:473–498.)

Depending on LV geometry and size and the physical characteristics of the mitral valve, surgical repair may bring the anterior leaflet and the coaptation point of the valve into close approximation with the interventricular septum and the LVOT. That septal coaptation point can narrow enough to create a gradient in the outflow tract, so that the anterior leaflet is pulled into the LVOT by the Venturi effect, leading to obstruction and secondary mitral insufficiency (see Fig. 54.36). This anterior displacement of the mitral coaptation point and the amount of the extra anterior leaflet have been proposed to be mechanisms for SAM, thus leading to the development of surgical techniques that can reduce the incidence of SAM in high-risk patients.[364] Anesthetic management of obstructive cardiomyopathy centers on fluid and pharmacologic interventions to decrease the magnitude of the obstruction and, at the same time, lessen the severity of the mitral insufficiency. Most patients with outflow tract abnormalities have normal to supranormal contractility.

Generally, inotropic agents should not be used. The thick, hypertrophied ventricle usually has reduced compliance and is very load sensitive, so that outflow tract obstruction increases in hypovolemic conditions. Thus, optimizing preload and ventricular filling is appropriate both in managing the patient with LVOT and in assessing the need for surgical reconstruction of the LVOT, mitral valve repair, or both. Afterload reduction should be avoided because it worsens the obstruction. Conversely, increasing the afterload decreases the trans–outflow tract gradient and leads to a reduction of SAM and outflow tract obstruction. Hence, vasoconstrictors such as phenylephrine and vasopressin should be considered. In both congenital and iatrogenic LVOT obstruction, the degree of obstruction is dynamic. Obstruction is exacerbated by hypercontractile states and elevations in heart rate; therefore, reducing the heart rate with β-adrenergic blockade should be considered.

Continuous, skilled echocardiographic assessment and interpretation are important for optimal intraoperative management of these patients. Assessing the severity and mechanism of outflow tract obstruction and determining whether to reinstitute CPB to revise the repair or replace the valve are not innocuous decisions, and they must be carefully made jointly by the anesthesiologist and the surgeon, ideally with input from the appropriate cardiologist.

Minimally Invasive Mitral Valve Surgery. Cosgrove, Sabik, and Cohen were among the first surgeons to modify the traditional approach to cardiac surgery and pioneer the concept of minimally invasive cardiac surgery.[365] The rapid development and refinement of minimally invasive techniques have resulted in the realizations that minimally invasive cardiac surgery does not compromise patients' safety or surgical exposure and that results are comparable to those of traditional open procedures. Mihaljevic and colleagues published a series of 1000 minimally invasive valve operations performed between 1996 and 2003, and noted the following benefits: reduced bypass and cross-clamp times, reduced stroke and MI rates, reduced length of hospital stay, and a higher rates of discharge home rather than to another facility.[366]

Access to the mitral valve through minimally invasive techniques can be through a lower hemisternotomy, a right parasternal incision excising the cartilaginous portions of the third and fourth ribs, or a right thoracotomy through a 4-cm incision.[367] The mitral valve is then exposed through the left atrium or by a transseptal approach through the right atrium. Visualization of the valve for repair or replacement can be achieved in the following ways: by direct inspection and instrumentation; by "port access" under thoracoscopic guidance and video assistance; or by a more complete endoscopic technique using the DaVinci robotic system (Intuitive Surgical, Inc., Sunnyvale, CA). The DaVinci system uses robotic arms and instrumentation controlled by the surgeon sitting at a remote, computer-enhanced, three-dimensional imaging console to assist in completing the surgery.[368] The DaVinci robot set up on the patient is shown in Fig. 54.37.[369] Fig. 54.38 shows the surgeon's location in the operating room.[370]

Endoscopic or minimally invasive mitral procedures usually involve CPB with aortic and venous cannulas placed through the femoral artery and vein respectively. In addition, the surgeon may choose to use an endoscopic aortic occlusion device that allows a bloodless operative field

and the delivery of cardioplegia (Fig. 54.39).[371] As mentioned with total endoscopic coronary revascularization surgery, positioning of the EAOBC requires intraoperative fluoroscopy or echocardiography to confirm the catheter's position definitively. Known concerns and risks include catheter migration into the heart across the aortic valve and distal migration with occlusion of the brachiocephalic trunk.[372] Alternatively, the aorta can be occluded directly with flexible cross-clamps introduced through small chest wall incisions. The Chitwood transthoracic aortic cross-clamp (Scanlan International, Inc., St. Paul, MN) and the Cosgrove Flex Clamp (Cardinal Health, McGaw Park, IL) are being used for this purpose (Fig. 54.40).[367] Cardioplegia needles may be inserted under direct vision or thoracoscopic guidance.[372] Retrograde cardioplegia, although not necessarily used in all patients, can be accomplished by directly cannulating the coronary sinus with a retrograde catheter at the operative site (RA approach) or by placing a percutaneous coronary sinus catheter in the internal jugular vein and positioning it under echocardiographic guidance.

Secondary operative considerations include the unique positioning of the patient for the use of robotic instrumentation. Most minimally invasive approaches require a 30-degree "right side up" position.

Anesthetic management includes selective lung ventilation with the use of a double-lumen tube or bronchial blocker, if this is needed for surgical exposure. Monitoring considerations are similar to those for standard approaches to valvular heart surgery. Furthermore, a PA ventilation (PA vent) catheter is placed in a manner similar to placement of a PA catheter.[372] These two catheters differ in two important ways. First, the PA vent has a significant amount of transducer "noise" in the tracings due to its excessive compliance. Second, the PA vent has fewer ports and thus does not allow for CO measurement. Some surgeons prefer to place a PA vent in the field. In these cases the cardiac anesthesiologist can place a PA catheter, and derive the benefits of mixed venous blood sampling and CO measurement in addition.

The outcomes of minimally invasive mitral valve surgery have been encouraging. Although prospective trials comparing minimally invasive mitral valve surgery and standard approaches are limited, developments in technology and an integrated team approach may facilitate favorable postoperative outcomes.[367] Reports describe mortality and morbidity rates comparable to those of full-sternotomy approaches, with reduced postoperative bleeding and trends toward reduced length of hospital stay and a higher rate of discharge home.[370,373]

Aortic Valve Disease

Aortic Stenosis

PATHOPHYSIOLOGY. AS is the most common cardiac valve lesion diagnosed in the United States. Marked increases in the annual volume of aortic valve replacements have occurred recently, especially in older and high-risk patients.[374]

AS is often caused by congenital defects in the valve because congenital bicuspid aortic valve occurs in 1% to 2% of the population.[374] Inheritance has been found to play a role, with an autosomal dominant pattern and a variable penetrance.[375] Even a normally functioning bicuspid aortic valve tends to open and close with abnormal folding and creasing, leading to scarring and calcification which ultimately culminates in AS with or without aortic regurgitation (AR). Although patients with a bicuspid aortic valve are asymptomatic until late in the disease process, severe, symptomatic AS or AR may develop in midlife. In addition, the abnormal motion of the bicuspid leaflets causes some turbulent flow into the aorta, which eventually can lead to dilatation and subsequent rupture or dissection.[376,377] A typical "fish-mouth" or elliptical shaped opening of the aortic valve in a midesophageal, cross-sectional TEE view of the valve is a telltale sign of a bicuspid aortic valve.

Acquired AS is usually the result of senile degeneration with sclerosis and calcification of the valve. The prevalence of AS in the population is increasing. Approximately 3% of people over the age of 75 years have AS, and 12% of these have moderate or severe aortic stenosis.[374,378] A clear association is reported between clinical risk factors for atherosclerotic disease (e.g., the process of chronic inflammation) and the development of AS.[378,379] In developed countries, rheumatic disease is a less common cause of AS, and AS is usually associated with concomitant AR.

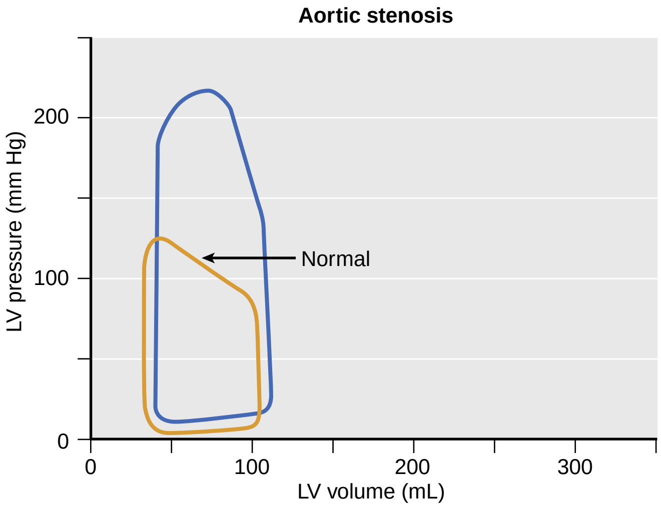

Fig. 54.41 Pressure-volume loop in aortic stenosis. *LV*, Left ventricular. (Modified from Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease. *Semin Anesth.* 1982;1:239.)

A typical pressure-volume loop for AS is shown in Fig. 54.41. In patients with AS, the obstruction of LV outflow increases peak systolic wall stress, resulting in chronic pressure overload that directly stimulates parallel replication of sarcomeres in the LV and consequently causes concentric ventricular hypertrophy. The peak pressure generated by the LV during systole is much higher than normal because of the high transvalvular pressure gradient. Concentric LV hypertrophy nearly always develops as a result of the increases in pressure load (Fig. 54.42). This increased load also leads to diastolic dysfunction, an increase in LVEDP, and subendocardial ischemia.

Echocardiography and intraoperative TEE in particular play important roles in the diagnosis and ultimate management of patients with AS, both in the outpatient setting and during surgical aortic valve replacement. The severity of AS can be assessed from various echocardiographic parameters. One that is commonly used is the aortic valve area (AVA). The normal range of the AVA is 3 to 4 cm^2; AS is graded as severe if the AVA is reduced to 1 cm^2 or less.[380] Another parameter commonly used to determine the severity of AS is the gradient across the aortic valve; AS is considered severe if the mean gradient is greater than 40 mm Hg.[355] Echocardiography can be used to examine multiple aspects of the pathophysiology of AS, including the severity of AS, any structural abnormalities of the valve causing LVOT obstruction, any ascending aortic pathology, and any concomitant heart valve lesions.

With TEE, the best views for evaluating the aortic valve are the midesophageal aortic valve short-axis view, the midesophageal long-axis view, and the transgastric views. Midesophageal views are helpful in ascertaining the shape of the aortic valve and the two-dimensional anatomy of AS (Fig. 54.43), whereas transgastric views are helpful in obtaining gradient measurements across the valve and the LVOT (Fig. 54.44). In addition, both the midesophageal and

the transgastric views can be used to measure the dimensions of the aortic valve annulus and the LVOT; these measurements are helpful in making surgical decisions related to the size of the valve.

Patients with AS who have not yet developed symptoms should be closely monitored over time for progression of the disease. Patients who develop symptoms (including decreased exercise tolerance and exertional dyspnea, angina, CHF, and syncope) are considered for valve replacement. A delay in surgical intervention in symptomatic patients can worsen their prognosis.[378]

Anesthetic Management. Premedication may alleviate a patient's anxiety regarding cardiac surgery, and it helps to prevent perioperative tachycardia in patients with AS. Monitoring in these patients includes standard noninvasive modalities and invasive monitoring of blood pressure and CVP. Depending on the severity of the AS, pulse pressure may be as low as 50 mm Hg or less. TEE is indicated for monitoring and the measurements obtained yield extremely valuable information (Fig. 54.45; see also Figs. 54.43 and 54.44).[381,382]

Insertion of a PA catheter may be considered to monitor PAP and CO during surgical procedures, but is rarely needed in patients with normal ventricular function. Patients with AS are at increased risk if arrhythmias develop during PA catheter placement as coronary perfusion can be severely compromised. Furthermore, if cardiopulmonary resuscitation is needed, chest compressions do not generate effective CO across the stenotic valve.

The anesthetic management of patients with AS should not involve any medication that could have negative inotropic, tachycardic, or vasodilatory effects. Furthermore, every effort should be made to ensure that the patient stays in sinus rhythm. In patients with AS, the atrial kick may contribute as much as 40% of the total CO.

Table 54.19 summarizes the goals of anesthetic care of a patient with AS.

Aortic Regurgitation

Pathophysiology. AR is the flow of blood from the aorta backward into the LV during the diastolic phase of the cardiac cycle. Chronic AR is more prevalent than acute AR and has compensatory physiologic changes, whereas acute AR is not handled well hemodynamically. However, the precise prevalence of AR—acute and chronic—remains unknown.[383]

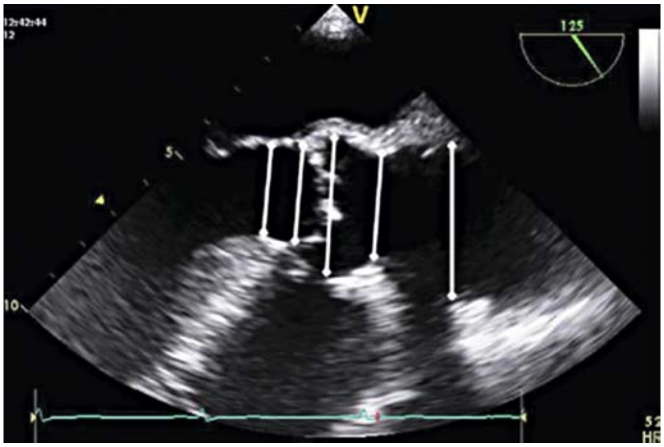

Fig. 54.45 Intraoperative transesophageal echocardiographic measurements of the aortic valve annulus, including the diameter of the left ventricular outflow tract (to exclude severe asymmetric septal hypertrophy), aortic valve annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta *(arrows, from left to right).* (From Pasic M, Buz S, Dreysse S, et al. Transapical aortic valve implantation in 194 patients: problems, complications, and solutions. *Ann Thorac Surg.* 2010;90:1463–1469; discussion: 1469–1470.)

Causes of chronic AR include congenital lesions, degenerative processes, and rheumatic disease, but idiopathic causes seem to be the most common.[383] These processes cause malcoaptation of the aortic valve leaflets by producing abnormalities in the leaflets themselves or dilation of the aortic valve annulus, the aortic root, or both. Abnormalities of the aortic valve leaflets include congenital conditions (e.g., bicuspid aortic valve), endocarditis, rheumatic heart disease, inflammatory diseases, certain connective tissue diseases, and chest wall trauma causing injury to an aortic valve leaflet. Dilation of the proximal aortic root may be caused by annuloaortic ectasia resulting from long-term chronic hypertension or simply from the normal aging process.[384] Other aortic valve annular or aortic root causes of AR include Marfan syndrome, syphilis, congenital diseases such as osteogenesis imperfecta and Ehlers-Danlos syndrome, and idiopathic causes.[383,384]

Chronic Aortic Regurgitation. Patients with chronic AR may remain asymptomatic for years or even decades. The LV undergoes a process of remodeling resulting from series replication of sarcomeres and the development of eccentric ventricular hypertrophy and chamber enlargement in the presence of a chronically increasing volume of regurgitation (see Fig. 54.42). Although the pressure-volume loop is shifted far to the right in patients with chronic AR, the LVEDP remains relatively normal because the LVEDV increases slowly (Fig. 54.46). Forward flow is improved by peripheral vasodilation. Typically, a normal EF is maintained by a large stroke volume. However, over time, increases in LV wall stress and afterload result. Eventually, as LV dilation and hypertrophy progress, irreversible LV dysfunction develops, and patients become symptomatic. As a compensatory mechanism for poor CO, sympathetic constriction of the peripheral vasculature occurs to maintain blood pressure, but this adaptation exacerbates regurgitation and further reduces CO.

In addition to a detailed history and physical examination, diagnostic modalities such as magnetic resonance imaging, radionuclide angiography, and exercise stress testing are used to assess AR. However, echocardiography remains the most important diagnostic tool (Fig. 54.47). The severity of AR is assessed as follows: regurgitation of less than 20% of the total LV stroke volume is considered mild, 20% to 39% is considered moderate, 40% to 60% is considered moderately severe, and more than 60% is considered severe.

Several semiquantitative echocardiographic modalities are used to assess AR. These include color flow mapping, in which the ratio of the AR jet width to the width of the LVOT is used to ascertain the severity of the condition. Jets that appear to be central in flow may appear to be larger than

LV, Left ventricular.

From Townsley MM, Martin DE. Anesthetic management for the surgical treatment of valvular heart disease. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:327.

they actually are because of the entrainment of fluids.[383] This possibility should be considered when one is evaluating a centrally directed jet as compared with an eccentrically directed jet. The vena contracta, the narrowest part of the regurgitant jet, can be measured to determine the severity of AR (see Fig. 54.47). A vena contracta measurement of 6 mm or greater carries a sensitivity of 95% and a specificity of 90% for the presence of severe AR.[385] A vena contracta of less than 3 mm indicates mild AR. The pressure half-time of the AR jet can be measured echocardiographically. A pressure half-time of less than 200 ms indicates severe AR, while a pressure half-time of greater than 500 ms indicates mild AR. In addition, holodiastolic flow reversal in the descending aorta signifies moderate-to-severe AR.

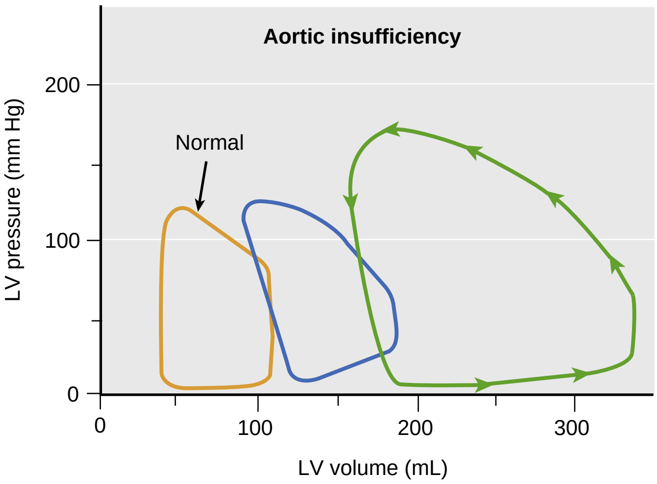

Fig. 54.46 Pressure-volume loop in aortic regurgitation (AR). Acute AR, *middle loop;* chronic AR, *right loop. LV,* Left ventricular. (Modified from Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease. *Semin Anesth.* 1982;1:239.)

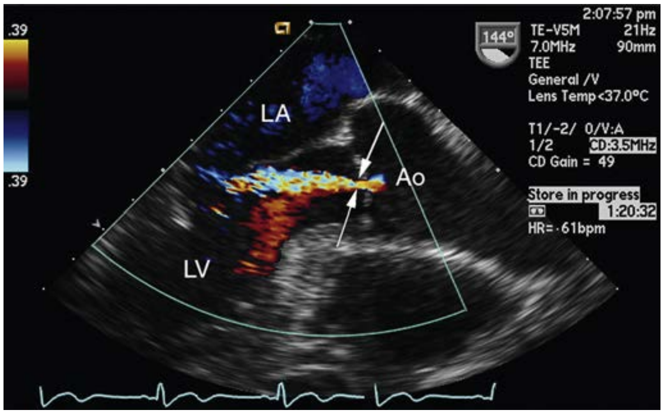

Fig. 54.47 Vena contracta. Calipers measure the narrowest portion of the aortic regurgitant jet, which corresponds to an approximation of the regurgitant orifice area. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle. (From Perino AC, Reeves ST, eds. *A Practical Approach to Transesophageal Echocardiography.* 2nd ed. Philadelphia; Lippincott Williams & Wilkins; 2008:232.)

Although patients with chronic AR can remain asymptomatic for decades, symptoms of left-sided HF eventually occur, such as exercise intolerance, dyspnea, and paroxysmal nocturnal dyspnea or orthopnea. Afterload reduction may become necessary as the disease progresses. In addition, a few patients present with angina despite having normal coronary arteries; this angina results from poor coronary perfusion resulting from low diastolic aortic pressure. A difficult decision for the cardiologist is at what point in the course of the disease surgery should be performed to prevent the development of irreversible LV dysfunction, especially in patients with severe chronic AR.[382,383]

ACUTE AORTIC REGURGITATION. Acute AR is less common than chronic AR but carries a more ominous prognosis. Common causes of acute AR include trauma, bacterial endocarditis, and aortic dissection. Rarely, acute AR occurs as an idiopathic complication, such as after aortic valvuloplasty. The pathophysiology of acute AR is that an acute volume load compromises the LV. Because the LV has not had time to undergo the process of eccentric hypertrophy, as it does in chronic AR, it is unprepared to accommodate this sudden increase in volume. As shown in Fig. 54.46, this sudden increase in the LVEDP causes a rightward shift in the pressure-volume loop.[384] A sympathetic response is activated; tachycardia and an increased contractile state are the chief compensatory mechanisms for maintaining adequate CO. Unless acute AR is managed appropriately, these compensatory mechanisms rapidly fail. Furthermore, the sympathetic response causes sympathetic constriction of the peripheral vasculature, thereby increasing SVR and further worsening the AR. LV function can deteriorate rapidly, necessitating emergency surgery. Vasodilator therapy may temporarily stabilize the patient during transport to the operating room.[383]

ANESTHETIC MANAGEMENT. The anesthetic management of patients with AR should include maintaining a relatively fast heart rate (≈90 beats/min) and a relatively low SVR while maintaining preload and contractility. Table 54.20 summarizes the goals of anesthetic care for a patient with AR. Light premedication is recommended. Regarding the choice of drugs for general anesthesia in these patients, medications that cause bradycardia or high blood pressure should be avoided because these changes worsen the degree of AR and can precipitate LV failure.

Preoperative placement of an arterial catheter and central venous catheter is standard, and a PA catheter may

TABLE 54.20 Pathophysiologic Changes Associated With Aortic Regurgitation

LV, Left ventricular.
From Townsley MM, Martin DE. Anesthetic management for the surgical treatment of valvular heart disease. In: Hensley FA, Martin DE, Gravlee GP, eds. *A Practical Approach to Cardiac Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:335.

be considered if PAPs are high or ventricular function is compromised. In the prebypass period, TEE allows the anesthesiologist to determine the cause and severity of the AR, evaluate LV size and function, and assess the function of the other cardiac valves. Furthermore, TEE assessment in the immediate postbypass period confirms the proper positioning and function of the new aortic valve.

Weaning from CPB may be complicated by preexisting LV dysfunction. Furthermore, mechanical aortic valve replacement results in a mild transvalvular pressure gradient. Therefore, inotropic agents may be needed to improve LV function. Preload augmentation must be continued to maintain the filling of the dilated LV.

Minimally Invasive Aortic Valve Surgery. The surgical approach to the aortic valve can be made through several different incisions, including a right parasternal incision, upper hemisternotomy, or lower hemisternotomy.[365] Because surgical exposure is limited, transcutaneous defibrillator pads should be placed before preparing and draping, should the need to defibrillate arise.[372]

Placement of CPB cannulas from distant sites is a hallmark of minimally invasive surgery and speaks to the importance of TEE guidance led by the anesthesiologist. To achieve arterial access, a surgical decision may be made to cannulate the femoral artery.[373] Alternatively, if aortic atheromatous disease precludes retrograde aortic arterial flow, the surgeon may attempt aortic cannulation through an incision directly into the aorta, or through the axillary artery.[370,372] Venous bypass drainage can be accomplished by cannulating the right atrium (if surgical exposure is not compromised) or through the femoral vein. Positioning of the distal drainage portion of the femoral vein cannula in the IVC, right atrium, or distal segment of the SVC is guided and confirmed by TEE (Fig. 54.48).[373] To reduce the incidence and magnitude of retained intracavitary LV air, carbon dioxide can be insufflated into the surgical field.[370]

In general, anesthetic monitoring considerations are similar to those for standard approaches to valvular heart surgery. However, in the absence of direct visualization of the heart, TEE is even more valuable for assessing cannula positioning and ensuring adequate ventricular deairing.[372] If retrograde cardioplegia is required, TEE may be used to guide a transjugular retrograde catheter into the coronary sinus.

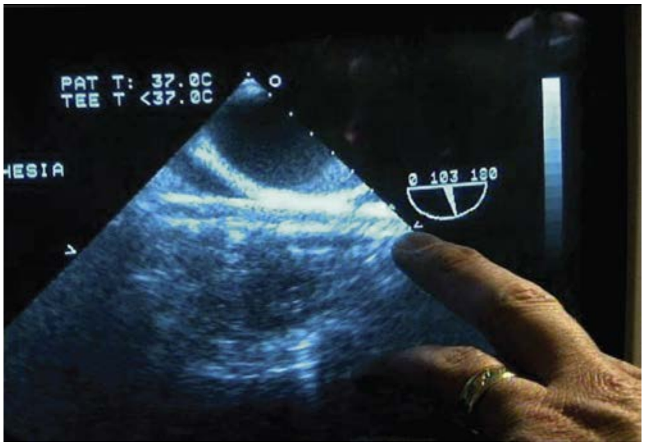

Fig. 54.48 Venous cannula placement through the inferior vena cava–right atrium into the superior vena cava.

One report of a large series of minimally invasive aortic valve procedures included more than 900 patients. Compared with the national average, these patients had decreased blood product use (with 53% of first-time aortic valve surgery patients receiving no blood products) and higher rates of discharge home (including 40% of the octogenarian patients).[386]

Other Valvular Disease

Tricuspid Valve Disease. Right-sided valvular disease in adults is most often a manifestation of increased pulmonary pressures (e.g., secondary to intrinsic lung disease, pulmonary vascular disease, or left-sided cardiac disease), but it can also result from rheumatic, traumatic, infectious, humoral, and/or neoplastic processes.

Tricuspid Regurgitation. Tricuspid valvular disease in adults is predominately regurgitant. Though it may be well-tolerated when mild-moderate, patients with significant TR will eventually demonstrate signs and symptoms of elevated RA pressure (e.g., hepatomegaly, peripheral edema, ascites). Compensatory changes with long-standing TR involve RV and RA chamber dilatation, and possibly atrial fibrillation. Long-standing TR and RV enlargement will progressively result in RV systolic dysfunction due to the alteration in RV geometry, which leads to further tricuspid annular dilation, worsening of TR severity, and further RV enlargement. TR has been categorized into stages based on severity and secondary findings of importance with implications regarding the manner of repair once indicated.[387]

- Stage 1: initial annular dilatation secondary to RV enlargement. TR is not usually significant.
- Stage 2: progressive annular dilatation results in poor leaflet coaptation. TR is significant. RV dilatation is more pronounced.
- Stage 3: severe RV dilatation and dysfunction, with tethering of tricuspid leaflets due to RV dilatation causing severe TR

If the tricuspid insufficiency is secondary to RV pressure overload states, as with pulmonary hypertension, RV hypertrophy also ensues. This hypertrophy and increased RV pressure can lead to leftward displacement of the interventricular septum and impaired LV systolic and diastolic performance.

Primary or structural TR results in morphological abnormalities of the leaflets themselves as a result of rheumatic, traumatic, infectious, humoral, and/or neoplastic processes. Secondary or functional TR is the most commonly observed etiology of TR in Western countries,[388] and can be a sequelae of left-sided cardiac disease that results in elevated pulmonary vascular pressures, cor pulmonale, and/or primary pulmonary hypertension. Functional TR is most often the result of a dilated tricuspid annulus (the tricuspid leaflets are morphologically normal), and is frequently present in patients undergoing aortic, and particularly mitral, valve surgery. It has long been known that a small degree of TR can be demonstrated in about 70% of normal individuals, but it remains somewhat controversial to conclude that it is therefore normal to have TR. What is not in debate, however, is that TR leads to progressive right-sided volume overload and progressive annular dilatation that will not spontaneously remodel following repair of left-sided valvular lesions, and may even continue to dilate further.[389]

Severe TR is a predictor of long-term mortality (65% 1-year survival rate in patients with severe TR compared with 90% of patients without TR),[390] and thus is now considered a class I indication in both American and European guidelines for concomitant tricuspid valve repair or replacement in patients undergoing left-sided heart valve surgical procedures. Tricuspid annular dilatation alone with lesser degrees of TR is considered a class II indication for tricuspid valve repair or replacement in patients undergoing left-sided heart valve surgical procedures.

TR impairs the ability of the RV to pump blood through the lungs and across to the left side, so the main anesthetic management consideration for the patient with TR is preload preservation. The most effective management strategy to improve forward flow from the RV derives from the principle of ventriculoarterial coupling, which holds that no matter how compromised the intrinsic systolic mechanics of a pumping chamber may be, its ability to function as a pump will generally be improved by reducing the afterload against which it must pump. Thus, reductions in PVR (e.g., with nitric oxide or inhaled prostaglandins) can help to optimize RV function, decrease TR, and get blood across the pulmonary bed to the left side. High-normal heart rates, maintenance of atrial kick, and judicious use of inotropes or inodilators will also help optimize forward flow from the RV as needed. Repair of functional TR usually entails either surgical annuloplasty (e.g., with a ring or band) or bicuspidization, either of which are usually successful in decreasing the amount of TR, but which can sometimes leave mild residual TR or create an elevated pressure gradient across the tricuspid valve if the annular size is excessively downsized.[385]

TRICUSPID STENOSIS. Tricuspid stenosis (TS) is a relatively rare clinical finding in adults. Patients with TS may have significant RA enlargement and possibly atrial fibrillation. Chronic elevation of RA pressure leads to IVC dilatation, jugular venous distention, and hepatic congestion. Clinical symptoms and signs can include hepatomegaly (with or without hepatic dysfunction), ascites, peripheral edema, fatigue, and dyspnea.[385,391]

TS results in reduced RV filling. The normal tricuspid valve area is 7 cm^2, and ventricular filling is compromised once the valve area falls to less than 1.5 cm^2. The severity of TS is usually assessed echocardiographically by measuring the Doppler-derived transvalvular gradient. Mild TS is associated with a gradient of 2 mm Hg or less; moderate TS, 2 to 6 mm Hg; and severe TS, greater than 6 mm Hg.[392]

Anesthetic management centers on maintaining preload and controlling heart rate. Overt tachycardia should be avoided because it significantly shortens the interval for diastolic filling, which is necessary in these patients. The target heart rate is not frank bradycardia, because CO may not be optimal, but the heart rate should be in the low-normal range. When atrial fibrillation is not part of the clinical picture, preserving AV synchrony is important for maintaining RV preload and CO. Although RV inotropic failure is not usually a major concern in isolated TS, it may be when TS is a part of multivalvular heart disease or ischemic heart disease, thus warranting consideration of inotropic support. SVR should be maintained because the fixed obstruction at the level of the tricuspid valve prevents a compensatory increase in preload if afterload declines.

Pulmonic Valve Disease. Pulmonic valvular disease can be congenital or acquired, with congenital etiologies responsible for the vast majority of the cases. Previous pulmonic valve surgery is not an infrequent etiology of pulmonic valve disease in adults.

PULMONIC STENOSIS. Pulmonic stenosis (PS) *as an entity* entails an obstruction to right-sided CO, with the obstruction potentially located at the subvalvar level (just below the valve in the RVOT), at the level of the valve itself, or supravalvar (above the valve in the main PA). Valvular PS is caused by congenital valve abnormalities in 95% of cases,[385] but isolated valvular PS is relatively rare as a congenital lesion. Acquired etiologies in adults include carcinoid disease, rheumatic disease, and prior pulmonic valve, RVOT, or main PA procedures. This would include a prior Ross Procedure (to correct congenital AS) in which the pulmonic valve is translocated to the aortic position and a homograft is implanted in the pulmonic position. Elevated transvalvular pressure gradients may lead to RV hypertrophy, RV and tricuspid annular dilatation, TR, and possibly eventual RV failure. Treatments for valvular PS include percutaneous balloon valvuloplasty, surgical valvotomy, RV to PA conduits, and surgical or percutaneous valve replacement. However, recent data indicate that the currently available percutaneous transcatheter pulmonic valve "may not be able to adequately address a subset of patients with complex RVOT morphology."[393] Medical management strategies for valvular PS include judicious heart rate control, preload maintenance, and inotropic support as a bridge to percutaneous or surgical intervention. Supravalvular narrowings are often amenable to percutaneous dilatation and/or stenting. Subvalvular muscular infundibular obstruction may occur naturally in tetralogy of Fallot (and is generally relieved by afterload augmentation with or without volume loading as needed). Infundibular obstruction can also result from chronic long-standing PS. As with dynamic LVOT obstruction, tachycardia and hypovolemia can precipitate a dynamic clinical condition in which RVOT obstruction is accentuated. Dynamic RVOT obstruction is managed as for dynamic LVOT obstruction, with preload maintenance, afterload augmentation, control of heart rate, and avoidance of an enhanced inotropic state.

PULMONIC INSUFFICIENCY. Pulmonic insufficiency (PI) can result when the pulmonic valve is rendered incompetent in childhood during balloon valvuloplasty for congenital PS or during surgical valvotomy for tetralogy of Fallot. PI may also be associated with rheumatic heart disease, pulmonary hypertension, pulmonary embolus, carcinoid syndrome, trauma, Marfan syndrome, idiopathic dilation of the pulmonary trunk, and endocarditis.[385] A common cause of mild PI is left-sided disease resulting in pulmonary hypertension. Most patients are asymptomatic, but long-standing severe PI can lead to symptomatic RV dilation and failure, warranting replacement of the pulmonic valve.

Anesthetic management requires being mindful of the primary cardiac or pulmonary disease that led to the pulmonic valvular insufficiency. In primary PI, anesthetic management goals may include maintaining preload, supporting contractility, and reducing PVR through ventilatory maneuvers and/or initiation of selective pulmonary vasodilatation (e.g., with nitric oxide or inhaled prostaglandins).

Minimally invasive surgical approaches can also be used to treat tricuspid valve disease,[394] as well as ASDs. Minimally invasive approaches to heart surgery are best accomplished through careful design of a hybrid operating room.

Structural Heart Procedures

Hybrid Operating Room. To address the technologic and procedural demands regarding surgical and imaging equipment for selected endovascular and transcatheter procedures, hybrid operating rooms have been built in many institutions. These rooms have complete dual capabilities for procedures that require fluoroscopy, open surgery, or both. Ideally, such rooms are within or adjacent to the regular surgical suite. The physical location of such hybrid rooms may represent an advance in care in that key personnel are more readily available to handle unanticipated complications and emergencies.

The types of procedures that are performed in the hybrid operating room vary according to institutional preferences but may include (1) electrophysiology procedures, (2) percutaneous management of valvular lesions, (3) placement of occlusion or umbrella devices to close intracardiac defects or communications, (4) placement of percutaneous VAD, (5) left atrial appendage (LAA) occlusion device placement, and (6) stenting of abdominal or thoracic aortic aneurysms.[395-397]

Although requirements vary depending on the nature of the procedure, sedation or general anesthesia along with monitoring by an anesthesiologist improves the efficacy and safety of many procedures.[398] Providing stable hemodynamics for organ perfusion and preservation during the procedure is an important goal. Some procedures can be performed with the aid of monitored anesthesia care or regional blocks, provided a certain patient comfort level can be achieved; however, in many cases, a general anesthetic regimen may be the best option. If indicated, general anesthesia with endotracheal intubation provides a controlled situation: the patient's comfort is maximized, and the airway is secured.[399] Use of a laryngeal mask or a standard mask airway is also possible, but the constant diaphragmatic movements that occur during spontaneous ventilation may interfere with fluoroscopic visualization of cardiac and vascular structures. In the absence of significant complications or comorbid conditions, the patient may be allowed to emerge from anesthesia before being transferred to a recovery area. In more complex cases, the patient may be transferred to an ICU and a slower emergence from general anesthesia can take place.

Most percutaneous procedures that are performed with fluoroscopic and TEE guidance are performed with the patient under general anesthesia. These include mitral valve repairs and many TAVI procedures where sternotomy and CPB are avoided, yet TEE is crucial to the performance and evaluation of the procedure.[396] Percutaneous closure devices, such as for ASDs and VSDs, and fenestrations are often performed with intracardiac echocardiography (ICE). If ICE or transthoracic imaging can be used, or imaging can be restricted to fluoroscopy only, procedures can be done with sedation.[397,398] Large-bore peripheral or femoral venous access is needed, and a radial arterial line is often placed.

Percutaneous VADs (TandemHeart, Cardiac Assist, Inc., Pittsburgh, PA, and Impella Recover LP 2.5 and 5.0, Abiomed, Inc., Danvers, MA) are placed in patients undergoing high-risk coronary interventions or ablation procedures or who are in cardiogenic shock.[397] These devices can almost fully support LV function and produce a CO with nonpulsatile blood flow. Thus, pulse oximetry and noninvasive blood pressure measurement may not work properly, and intraarterial line placement is recommended. Either sedation or general anesthesia can be used, depending on the patient's hemodynamic status and ability to cooperate. Large-bore intravenous access is desirable because a large amount of blood loss is possible. Surgical backup is necessary during these procedures.

Transcatheter Aortic Valve Implantation. Symptomatic patients with severe AS have a poor prognosis; the mortality at 1 year in medically treated patients is 50%.[400] Transcatheter aortic valve implantation (TAVI) was originally an alternative treatment option in patients with severe AS for whom cardiac surgery and traditional aortic valve replacement posed substantial risks, particularly patients of advanced age who have extreme comorbidities (e.g., porcelain aorta, prior radiation therapy, frailty, severe hepatic or pulmonary disease).[401-403] Now transcutaneous aortic valve replacement is being employed for treatment of patients categorized as moderate-risk patients, and trials are under way to study the procedure in low-risk patients.[404]

The technologic advances made in the development of TAVI procedures are ingenious. However, the procedure is associated with short-term and long-term morbidity, including mortality, stroke, need for permanent pacemaker insertion, vascular complications, valve embolization, renal failure, cardiac rupture, aortic rupture, cardiac tamponade, and bleeding.[405,406] Published guidelines regarding the TAVI procedure recommend specialized multidisciplinary heart teams that include cardiologists, cardiac surgeons, anesthesiologists, intensivists, nurses, and others.[404] The hybrid operating room or cardiac catheterization laboratory (CCL) where the procedure is performed must have adequate space, expert echocardiography, emergency supplies, support from colleagues, and immediate access to CPB technicians and a cardiac surgeon if necessary.

The TAVI procedure requires vascular access to the aortic valve annulus (Fig. 54.49).[407] Most procedures are performed using retrograde access via the femoral artery, however, other retrograde access can be accomplished using the subclavian or innominate artery or a direct ascending aortic approach. In cases where aortic disease or anatomy precludes a retrograde approach, anterograde access can also be performed through surgical exposure of the LV and a transapical approach. General anesthesia is needed for transapical procedures.[405] Large-bore intravenous access, an arterial catheter, and central venous access are essential, and a PA catheter may be used in patients with preexisting pulmonary hypertension. External defibrillation pads are placed and connected to the defibrillator before the procedure begins (ventricular fibrillation can result from manipulation of catheters within the heart or from rapid ventricular pacing).[405] Because a period of rapid ventricular pacing is required during deployment of certain of the valves, a transvenous lead for temporary pacing is inserted, typically through the femoral or subclavian vein (or, in the case of transapical procedures, sewn directly on the epicardial surface).[405]

When general anesthesia is used, a TEE probe is introduced after induction of anesthesia, so that structural anatomy can be confirmed after the TAVI procedure. A number of centers have adopted a minimalist approach to transfemoral TAVI in which sedation has replaced general anesthesia, and a fast-track protocol speeds the throughput of these patients. This has led it to be a "same-day" procedure in some sites with relatively good results, although these techniques are highly institutionally dependent and success is predicated upon the dynamics and experience of a well-trained team.[408,409]

The advantages of this approach include neurologic status monitoring, greater hemodynamic stability, and possibly reduced postprocedure length of stay in the ICU compared with an approach using general anesthesia.[410] However, if TEE is a planned part of the procedure to evaluate valve placement, aortic integrity, and to rule out cardiac complications, general anesthesia is suggested.

TEE has a central role in evaluating annulus size, aortic disease, ventricular function, and MR, as well as determining reasons for hemodynamic instability.[407,411] A balloon valvuloplasty of the aortic valve often precedes the insertion of a bioprosthetic valve, which is crimped on a valvuloplasty balloon catheter and implanted by inflation. The device is guided into position through the combined use of real-time TEE and fluoroscopy. Immediately after inflation, TEE is employed to measure the degree and source of any AR[412] and to examine the aorta for any aortic dissection.[407,411]

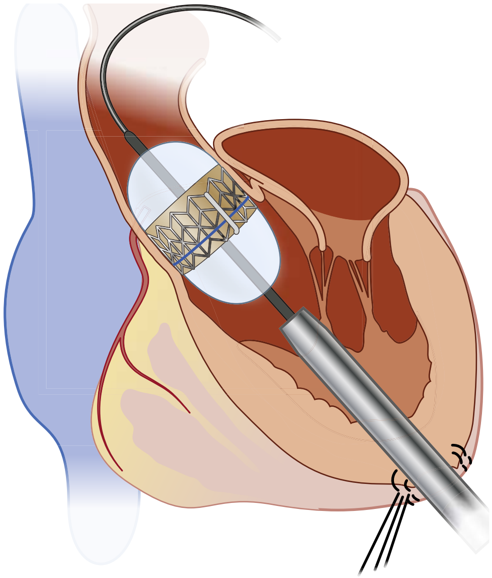

Fig. 54.49 Schematic of transapical aortic valve implantation. The prosthesis is implanted within the native annulus by balloon inflation. (From Walther T, Ralk V, Borger MA, et al. Minimally invasive transapical beating heart aortic valve implantation: proof of concept. *Eur J Cardiothorac Surg.* 2007;31:9–15.)

A major challenge during the TAVI procedure is maintaining hemodynamic stability. In patients with severe concentric LV hypertrophy and intravascular volume depletion, hemodynamic status may deteriorate rapidly because of ventricular pacing, intracardiac guidewire or catheter manipulation, or balloon aortic valvuloplasty itself.[405] Avoiding prolonged hypotension and the cycle of hypotension, subendocardial ischemia, and low output is critical to prevent hemodynamic collapse. The frequency and duration of rapid ventricular pacing episodes may need to be limited to allow enough time between episodes for spontaneous circulation to recover. Vasopressors (norepinephrine, epinephrine, or phenylephrine), administered as incremental boluses or as a continuous infusion, may be necessary. Constant communication among team members is essential throughout this multidisciplinary procedure.

The TAVI procedure requires state-of-the-art imaging capability, as well as the immediate availability of personnel to secure surgical access and institute CPB.[403] The short-term efficacy of TAVI, as shown by echocardiographic measurements, is good.[406] However, evidence on long-term outcomes awaits further data collection in national TAVI registries.[405,413]

Mitral Valve Clipping. Percutaneous mitral valve repair by clipping is a catheter-based procedure, in which edge-to-edge repair of the mitral valve is performed by the MitraClip (Abbott Inc., North Chicago, IL) (Fig. 54.50).[414] The MitraClip is used to perform mitral valve repair in patients who are considered too high-risk to undergo conventional mitral valve repair surgery. The percutaneous procedure is performed on a beating heart. TEE plays a crucial role in

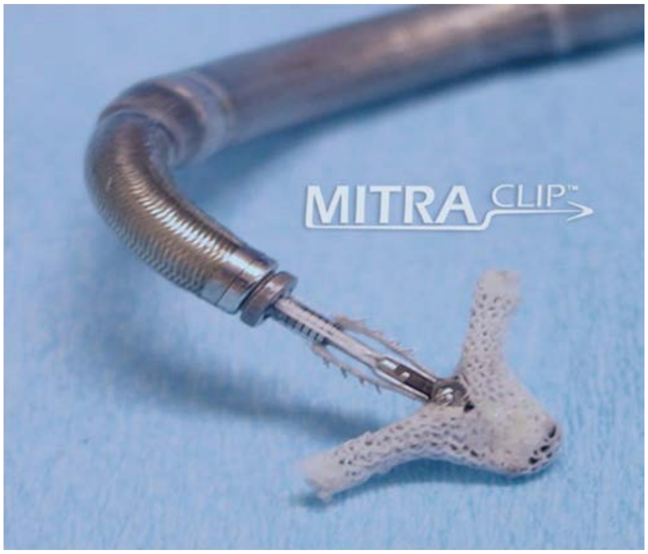

Fig. 54.50 Close-up view of the MitraClip (Abbott Inc., North Chicago, IL). (From Kothandan H, Vui KH, Khung KY, et al. Anesthesia management for MitraClip device implantation. *Ann Card Anaesth.* 2014;17[1]:17–22.)

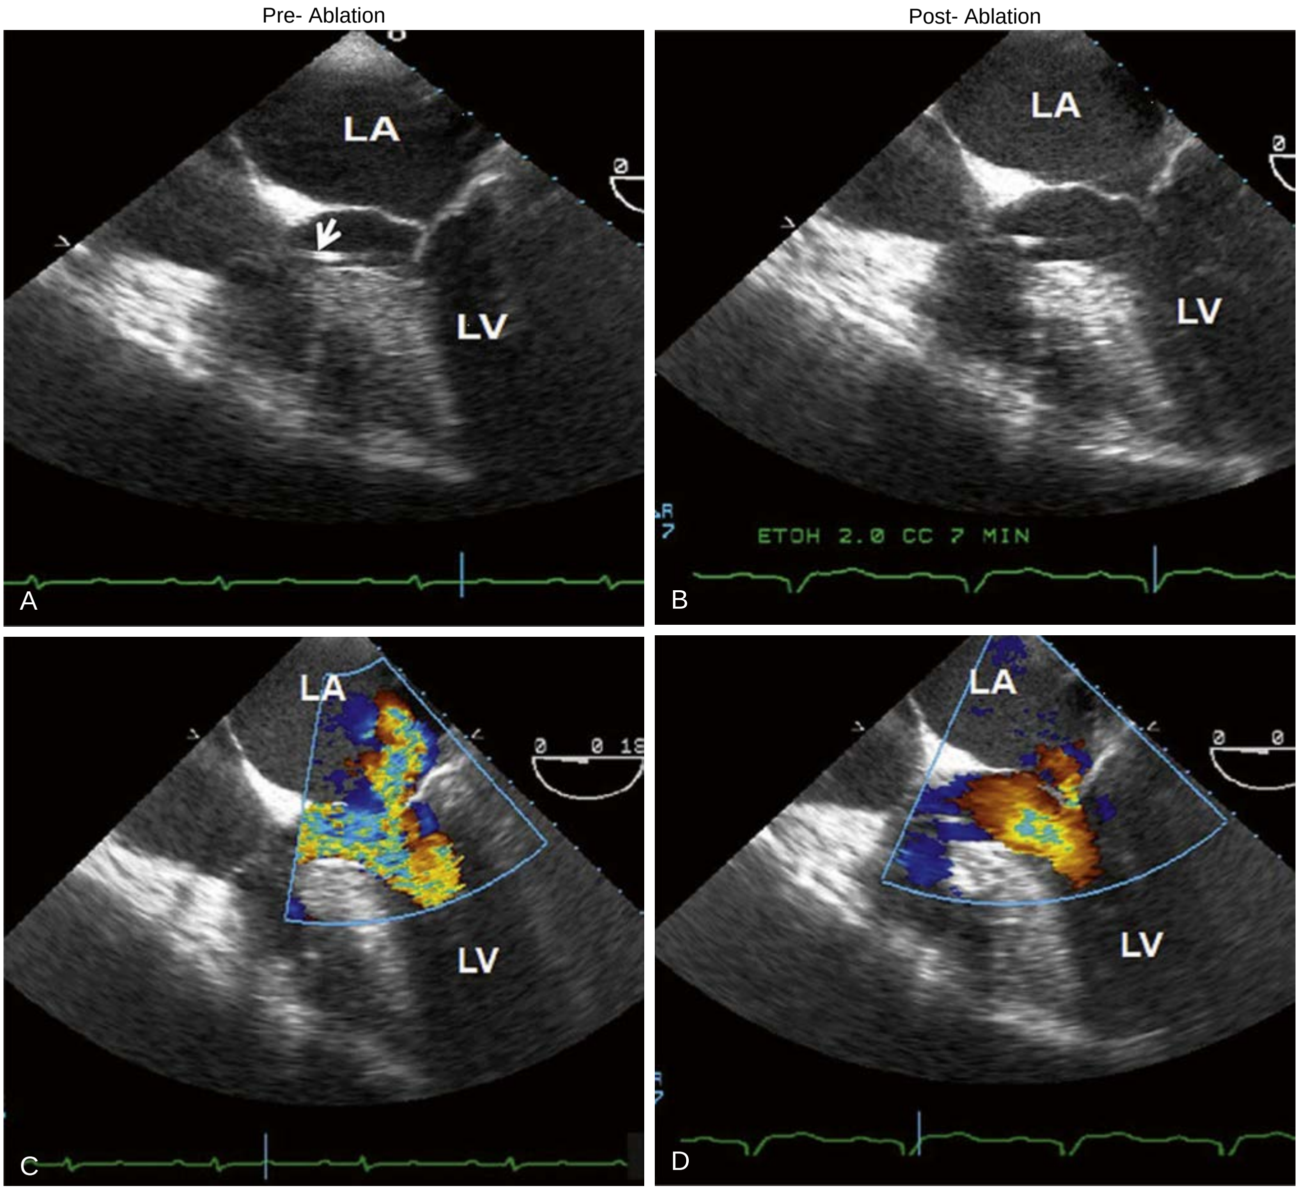

Fig. 54.51 Transthoracic echocardiography (TTE) shows images before and after MitraClip implantation in a patient with functional mitral regurgitation. 4-chamber views showing MR (A) before and (B) after MitraClip implantation. 2-chamber view showing MR before (C) and after (D) MitraClip implantation. *LA,* Left atrium; *LV,* left ventricle. (From Kothandan H, Vui KH, Khung KY, et al. Anesthesia management for MitraClip device implantation. *Ann Card Anaesth.* 2014;17[1]:17–22.)

directing the deployment of the device and placement of the clip(s). At the start of the procedure, 3D TEE is performed to provide pertinent annular and leaflet measurements. The device is advanced through the femoral vein and, after interatrial septal puncture, it is advanced into position under the guidance of TEE, taking care to avoid the atrial walls. A successfully performed MitraClip implantation produces a double orifice mitral valve (Fig. 54.51),[414] similar to an Alfieri repair, a mitral valve edge-to-edge stitch that is performed in the operating room with the use of CPB.[414]

MitraClip implantation has been shown to significantly reduce mitral regurgitation, improve the NYHA functional class of the patient,[415] and to shorten hospital stay relative to open cardiac surgery (Fig. 54.52). Potential problems associated with the procedure include worsening of the regurgitation, valvular stenosis, residual ASD, and rupture of the atrial wall with resultant tamponade.[414]

A multidisciplinary team comprised of a cardiologist, cardiac surgeon, cardiac anesthesiologist, cardiac specialty nursing staff, and a radiology technician is necessary to ensure success of these procedures.

Anesthetic Considerations. Mitral valve clipping is performed under general anesthesia with endotracheal intubation. Standard ASA monitors and arterial line for blood pressure monitoring are used. Two optimally functioning peripheral intravenous lines are generally considered adequate.

After the interatrial septal puncture is made, anticoagulation is achieved by administering heparin to achieve an ACT of approximately 250 seconds. Maintenance of ACT at

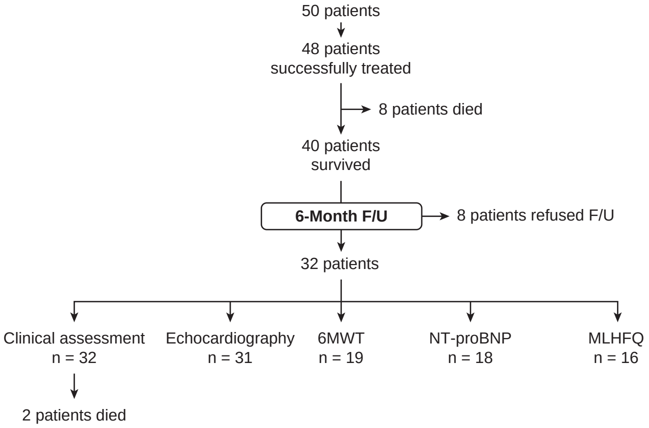

Fig. 54.52 Outcomes of MitraClip implantation at 6 months. Clinical follow–up was obtained from 32 and echocardiographic follow–up from 31 successfully treated patients at a median of 6.1 months (range, 4.2-10.4 months). Eight patients had died by the time of their scheduled follow–up visit, and eight patients did not return for a follow–up visit—one patient because he had received an LV assist device 3 months after MitraClip therapy and the others because they lived too far away from their respective treatment centers. Flow of patients over the 6–month period. *F/U*, follow–up; *MLHFQ*, Minnesota Living with Heart Failure Questionnaire; *6MWT*, 6–minute walk test. (Redrawn from Franzen O, van der Heyden J, Baldus S, et al. MitraClip therapy in patients with end-stage systolic heart failure. *Eu J Heart Fail.* 2011;13:569–576.)

an adequate level is ensured by checking the values every 30 minutes.[414]

During the procedure, ventilation holding may be required at certain critical points. Placement of a second clip may require special attention on the part of the cardiac anesthesiologist. During the advancement of the second clip from atrium to the ventricle there is a potential for damage to the first clip. Some patients may experience transient hypotension during this process, and the use of vasopressors might be needed to support the blood pressure. Blood pressure should be brought to patient's non-anesthetized state at the end of each grasp and before the release of the device to evaluate any residual regurgitation. This will eventually help determine if the clip can be deployed or an additional clip will be needed.[414]

At the conclusion, protamine is used to reverse anticoagulation and patients are typically extubated at the end of the procedure, unless there is a medical need to keep the endotracheal tube in place. All patients typically spend the first night after the procedure in an ICU, although trends toward fast-tracking and bypassing the ICU have permeated the mitral clipping procedures as well.

Left Atrial Appendage Occlusion Device Implantation. AF remains the most common arrhythmia. AF increases the risk of stroke by fivefold due to appendage thrombus embolization, and consequently carries significant morbidity and mortality.[416] Drugs commonly used for the prevention of thrombus formation include warfarin, factor Xa inhibitors, and direct thrombin inhibitors, which reduce the risk of stroke by 60%. Patients for whom anticoagulant medication is contraindicated would be candidates for LAA occlusion techniques, which are increasingly available.

The PROTECT AF clinical trial studied the Watchman LAA system (Boston Scientific Corporation, Natick, MA) under the hypothesis that AF patients can be protected from stroke with the Watchman as effectively as with systemic anticoagulation.[416]

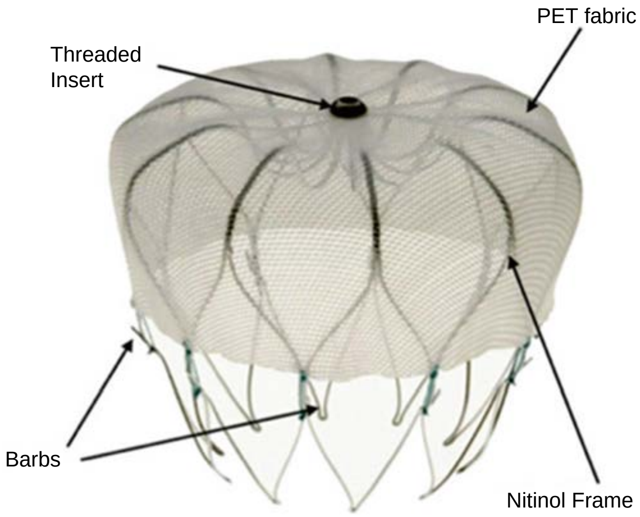

Fig. 54.53 Watchman device (Boston Scientific Corporation, Natick, MA), a self-expanding nitinol frame structure with fixation barbs and a permeable polyester fabric that covers the atrial facing surface of the device. (From Ding J, Zhu J, Lu J, et al. Transcatheter closure of the LAA: initial experience with the Watchman device. *Int J Clin Exp Med.* 2015;8[9]:15230–15237.)

Fig. 54.53[416] shows the Watchman device (Boston Scientific Corporation). Designed like a parachute, the Watchman device is deployed percutaneously from the femoral vein approach, and using TEE and fluoroscopic guidance, is directed across the interatrial septum and into the LAA. TEE is used extensively to evaluate the final deployment of the device and to confirm that there is minimal peri-device blood leakage.

Role of Transesophageal Echocardiography in the Watchman Procedure. Preprocedure TEE should be performed to rule out presence of a thrombus in the LAA, as it is a contraindication to the procedure. The presence of spontaneous contrast, on the other hand, is not considered a contraindication. TEE is further used to ascertain the shape of the LAA, the number and location of lobes of the LAA, and compared with the cardiac CT exam. In addition, the width of the orifice is measured using multiple viewing angles to determine the ideal landing zone, 10 mm distal to the ostium of the appendage. It is recommended that the device be sized 3-5 mm larger than the largest diameter.[417]

The device is advanced through a transseptal puncture. In order to align the device with the axis of the LAA the septal puncture is made in the inferior and posterior part of the fossa ovalis. Care must be taken to guide the device away from the aortic valve. The midesophageal aortic valve short-axis view and the midesophageal bicaval view can be used to ensure that the device is positioned near the IVC and is being advanced away from the aortic valve. After testing the device with a tug test and using color Doppler to rule out any significant perioccluder blood leakage, the device is finally released from the delivery cable.

Postimplantation it is important to perform a thorough TEE evaluation to rule out complications of implantation.

These complications may include left upper pulmonary vein compression, mitral valve impingement, and circumflex coronary artery compression.[417]

Anesthetic Management. LAA occluders are deployed under general anesthesia with endotracheal intubation. In addition to the standard ASA monitors, two large-bore peripheral intravenous lines are required for these procedures. At the time of septal puncture, heparin is administered to achieve a target ACT of greater than 250 seconds. Depending on the ACT toward the end of the procedure, heparin may be reversed with protamine. Generally, Watchman procedures are short in duration, in the range of 30 to 45 minutes. Patients are extubated on the table and are kept in the hospital overnight for observation after the procedure.

HEART FAILURE

HF can be defined as a complex clinical syndrome caused by any structural or functional cardiac disorder that impairs the ability of the heart (as a pump) to meet the metabolic demands of the body. Thus HF can result from an impairment of diastolic filling, systolic ejection, or both. Once HF is present, progressive cycles of deterioration and transient compensation ensue that may continue for years. Essentially, increases in end-diastolic volumes are compensated for by endogenously promoted diuresis, which is compensated for by sympathetic activation. This activation promotes further diuresis, which then requires compensation by further sympathetic activation, and so on. As the syndrome progresses, the hemodynamic changes, the cycles of fluid retention and relative hypovolemia, and bodily hypoperfusion perturb many neuroendocrine, humoral, and inflammatory feedback loops (Box 54.13), with resulting progressive and inexorable cycles of physical and functional deterioration of the heart and major bodily organs. In the United States, more than 6 million people currently have HF, and its prevalence is estimated at 10% in people older than 65 years. Although survival with HF has improved, the mortality associated with HF remains high, and at least 50% of patients with HF are expected to die within 5 years of diagnosis.

The ACC/AHA guidelines for the evaluation and management of chronic HF place patients in four classes based on the stages of the syndrome (Box 54.14).[418] Early in the course of the disease, ventricular contractility is maintained by adrenergic stimulation and activation of the renin-angiotensin-aldosterone and other neurohormonal and cytokine systems.[419,420] Patients in this stage would be considered to be in ACC/AHA class B. However, these compensatory mechanisms become less effective over time, and ventricular dilatation and fibrosis occur, progressively worsening cardiac function. This produces a chronic state of low perfusion and, ultimately, refractory end-stage HF, labeled class D in the ACC/AHA classification scheme. The New York Heart Association (NYHA) functional classification system is also used to assess the severity of functional limitations and correlates fairly well with prognosis (Box 54.15). Some patients may remain asymptomatic for years despite ventricular remodeling, dilatation, and decreased EF.

BOX 54.13 Pathophysiology of Heart Failure: From Injury to Clinical Syndrome

1. Causes
    a. Myocardial injury
        i. Ischemia
        ii. Toxins
        iii. Volume overload
        iv. Pressure overload
    b. Genetic perturbation
2. Cardiac remodeling
    a. Myocyte growth
        i. Concentric hypertrophy
        ii. Eccentric hypertrophy
    b. Interstitial fibrosis
    c. Apoptosis
    d. Sarcomere slippage
    e. Chamber enlargement
3. Clinical heart failure milieu
    a. Pump performance
    b. Circulatory dynamics

BOX 54.14 American College of Cardiology/American Heart Association Classification of Chronic Heart Failure Stages

A: High risk for heart failure
  Hypertension, diabetes mellitus, coronary artery disease, family history of cardiomyopathy
B: Asymptomatic heart failure
  Previous myocardial infarction, left ventricular dysfunction, valvular heart disease
C: Symptomatic heart failure
  Structural heart disease, dyspnea, fatigue, impaired exercise tolerance
D: Refractory end-stage heart failure
  Marked symptoms at rest despite maximal medical therapy

From Hunt SA, Abraham WT, Chin MH, et al. 2009 Focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines developed in collaboration with the International Society for Heart and Lung Transplantation. *J Am Coll Cardiol.* 2009;53:e1–e90.

BOX 54.15 New York Heart Association Heart Failure Symptom Classification System

NYHA Class Level of Impairment

I: Ordinary physical activity not limited by symptoms
II: Ordinary physical activity somewhat limited by dyspnea
III: Exercise limited by dyspnea during a mild workload
IV: Dyspnea at rest or with very little exertion

NYHA, New York Heart Association.

Medical Management of Heart Failure

Medical strategies for treating developing HF aim to limit disease progression, prolong life, and improve quality of life as the syndrome progresses. Medical therapies, such as ACEIs, β-blockers, diuretics, inotropic agents, and antiarrhythmics, represent the usual standard of care for HF patients. In general, β-blockers, ACEIs, and ARBs (for those who cannot tolerate ACEIs) are class I indications in the current ACC/AHA guidelines for class A and B patients with HF who have cardiac structural abnormalities and who have not yet developed symptoms of HF.[418] Signs and symptoms of HF (class C) are class I indications for the use of certain β-blockers that have been shown to prolong life (e.g., bisoprolol, carvedilol, and sustained release metoprolol), ACEIs, and ARBs. Diuretics and salt restriction should be added for patients with fluid retention. The implantation of devices for cardiac resynchronization therapy and defibrillatory capability is recommended, and revascularization and valve repair or replacement should be performed as appropriate. In both symptomatic and asymptomatic patients, current ACC/AHA guidelines list several additional potential therapies with class II and III indications.

However, even multidrug regimens may not prevent progression toward class D HF. A patient who has reached this category has a 2-year mortality risk greater than 75%. Thus, surgical intervention at less advanced stages of HF has become common in an attempt to prevent the inexorable progression of the syndrome.

Surgical Management of Heart Failure

In prior decades, the only established surgical treatment option for advanced HF was cardiac transplantation, which is still associated with excellent survival rates and functional capacity. It is now currently accepted that certain surgical interventions (in conjunction with pharmacological) have the capacity to retard or even potentially reverse the pathophysiology of cardiac failure. Though there are no large multicenter trials showing an independent effect on enhanced survival, specific surgical interventions (e.g., coronary revascularization, mitral valve repair/replacement) are now routinely performed for patients with advanced stages of HF to improve quality of life.

CAD is still the most common cause of HF, as it has been reported to be for many years. Where viable myocardium and feasible targets exist, revascularization of the failing heart can improve cardiac function and NYHA functional class.[421,422] It can also slow remodeling and decrease the incidence of arrhythmias,[423] and it has been demonstrated to improve survival. For example, Liao and associates found that among patients with CHF, survival was improved in patients who underwent revascularization compared with those who did not.[421] The optimal method of revascularization has not been conclusively determined, however, and studies continue to examine the issue of whether percutaneous coronary intervention is as effective as the gold standard intervention, CABG, in promoting long-term survival. The issue may be further complex in that certain subpopulations of patients benefit differently (e.g., those with diabetes), that surgical technique is not uniform, and that not all stents are equivalent. A meta-analysis demonstrated that in transplanted patients with HF from coronary allograft vasculopathy, patients who underwent percutaneous intervention instead of CABG had both a lower early mortality (PCI 4.3% vs. CABG 36.4%; $P < .001$) and a convincing trend regarding overall mortality (PCI 21.4% vs. CABG 42.3%; $P = .049$).[424]

Carefully selected patients with advanced CHF and MR receive several benefits from mitral valve repair or replacement. Among them are a progressive decrease in LVEDV, reverse remodeling, a progressive improvement in LVEF, improved functional status or NYHA class, improved 6-minute walk-test performance, improved peak oxygen consumption, and lower long-term mortality risk.[425,426] In fact, the 2017 focused update to the 2014 ACC/AHA Guidelines for the Management of Valvular Heart Disease provide several recommendations regarding surgical interventions for valvular dysfunction in the setting of HF.[427] Notably, a reminder is put forth in the guidelines that primary and secondary MR are different diseases. Primary (structural) mitral regurgitation is the subject of both curative and preventative recommendations. From a curative perspective, it is a class I recommendation that primary severe MR should be addressed surgically in the setting of LV dysfunction (LVEF 30%-60%) and/or LV end-systolic dimension (LVESD) ≥ 40 mm, to allow for reverse remodeling and to prevent further progression of disease. From a purely preventative perspective, it is a class IIa recommendation that severe asymptomatic primary MR be addressed surgically when the preserved LVEF progressively falls below 60% and/or the LVESD increases above 40 mm on serial exams. However, once LV dysfunction has progressed, it is only a class IIb recommendation that repair of symptomatic severe MR "may be considered" when the EF is less than 30%. The importance of appropriate patient selection is paramount, however, if optimal benefits are to be realized; the best results occur when mitral valve repair or replacement is undertaken before the geometric derangements to the LV and functional derangements of the valve reach certain levels. Several key predictors of lack of reverse remodeling have been identified: LV end-diastolic dimension greater than 6.5 cm, LVESD greater than 5.1 cm, large LA volume, high LV sphericity index, and severely depressed LVEF.[321,426-430] The optimal type of repair remains a subject of ongoing study, as does the issue of whether mitral repair or replacement affords the greater survival benefit to these often older and highly comorbid patients. Clearly, the quality of any repair greatly influences its outcome.

With respect to secondary, or functional, MR (most often secondary to ischemic disease), the 2017 ACC/AHA recommendations provide a class IIa recommendation for choosing chordal-sparing mitral valve replacement over "repair" for chronic severe MR in NYHA class III or IV patients. A 2016 trial of 251 patients with severe ischemic MR randomized to repair or replacement demonstrated no difference in reverse remodeling or mortality at 2 years, but an increased recurrence of moderate-severe MR with repair (vs. replacement) at 2 years, as well as an increased incidence of recurrent HF and rehospitalization for HF in the repair group.[431]

The effectiveness and potential survival benefits of combining revascularization with other surgical procedures (e.g., valve repair or replacement, ventricular reshaping) have been and continue to be the subject of large, multicenter investigations. Surgical ventricular restoration (reshaping), when performed in conjunction with revascularization, has thus far not been shown to improve survival, decrease symptoms, or increase exercise tolerance in patients with HF.[432]

In addition to common surgical interventions, electrophysiologic interventions (see chapter XX) play a key role in the initial modern management of HF. Large, international, multicenter trials in symptomatic and asymptomatic HF patients treated with cardiac resynchronization therapy, and/or ICD, have demonstrated improved survival, decreased risk of hospitalization, decreased incidence of sudden cardiac death, improvements in LVEF, decreased LV volumes, and decreased symptomatology.[433-437]

Today, when pharmacologic, electrophysiologic, and surgical interventions fail to stave off the inevitable progression of HF, mechanical circulatory support (MCS) with VADs is commonly implemented. Short-term MCS is generally used as a "bridge to immediate survival," a "bridge to recovery," a "bridge to next decision," and/or a "bridge to a bridge" after an acute cardiac event. Patients with advanced HF who have little expectation of ventricular recovery (or who have not recovered despite short-term support) now regularly receive intermediate- and long-term VAD support as a potential "bridge to transplantation" and a "bridge to candidacy." It is known that time spent on MCS can improve multisystem organ function to the point where previously transplant-ineligible patients can become transplant eligible. Since 2002, transplant-ineligible patients may receive approved LVADs as "destination therapy," a final treatment strategy shown to confer a survival advantage compared with medical management alone. Heart transplantation remains, of course, the ultimate surgical intervention for end-stage HF, but the number of patients with HF far exceeds the number of donor organs available each year worldwide, thus leaving MCS with an LVAD as the best option for most patients with advanced and end-stage HF.

The use of MCS with LVADs as a bridge to cardiac transplantation was previously shown to improve the survival rates and outcomes of patients with decompensated HF and was also found to improve multiorgan function during the time spent on VAD support.[438-443] This has been the rationale for the tremendous increase in the use of bridging technology.

However, analyses from the International Society for Heart and Lung Transplantation indicate that among patients who received cardiac transplants between July 2004 and June 2009, bridging to transplantation with pulsatile or nonpulsatile VADs did not actually confer a statistically significant survival advantage.[444] Those bridged patients who received a transplant between January 2002 and June 2009 actually had a worse 6-month posttransplant survival but an equivalent 7-year survival, to patients who were not bridged. However, the preponderance of deaths in the early years of this technology and the statistical methods used to perform the analyses may have great bearing on meta-analyses conducted in the modern era. Nevertheless a subsequent publication found that bridging to transplantation with an LVAD was associated with increased transfusion requirements for blood and blood products perioperatively, a higher incidence of clinically significant cell-mediated rejection within the first posttransplant year, and a trend toward increased postoperative mortality.[445] Further analyses are currently under way because overall, there does seem to be a survival advantage in more recent years with modern devices and our more extensive collective experience with patient management. Thus, the indication for bridging (e.g., elective vs. "required" because of severe decompensation) may be a vitally important part of the selection criteria going forward. In this regard, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) profile plays an important role in appropriate patient selection and the timing of intervention.[446] The INTERMACS profile characterizes patients with HF on the basis of clinical status and symptoms.[447]

- INTERMACS 1: critical cardiogenic shock
- INTERMACS 2: deteriorating on inotropes
- INTERMACS 3: stable, but inotrope dependent
- INTERMACS 4: symptomatic at rest
- INTERMACS 5: exertion intolerant
- INTERMACS 6: limited with exertion
- INTERMACS 7: advanced NYHA class III

With regard to destination therapy in the United States, the most recent statistics from the INTERMACS registry indicate that overall survival has dramatically increased since the introduction of continuous flow devices: 1-year survival is now approximately 80%, 2-year survival is approximately 70%, 3-year survival is approximately 60%, and 4-year survival is approximately 50%.[448] These numbers are extremely noteworthy considering the approximate 25% rate 1-year survival originally shown in the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial, which led to FDA approval of the HeartMate VE for destination therapy in September 2002.

The first generation of pulsatile VADs used as bridges to recovery and bridges to transplantation in the 1990s and early 2000s have now been supplanted worldwide by second- and third-generation, nonpulsatile devices, which generate continuous flow and have the advantages of being small, silent, valveless, and significantly more durable than the first generation of devices.

Though the current generation of devices is associated with a significant reduction in specific perioperative and long-term complications that were common with the first-generation pulsatile support devices, it seems that the total burden of "adverse events" has not apparently decreased because new complications have emerged that did not exist with the first generation of devices. Quality of life is arguably more important than quantity of life for many, and it is important to weigh the demonstrated clinical benefits of VADs against the risks of infection, pump malfunction (nowadays, most often due to pump thrombosis or electrical driveline issues), neurologic events, and bleeding complications. That said, the survival of end-stage HF is clearly better with MCS than without.

At the time of this writing, the most commonly used long-term LVAD in the United States is the HeartMate II (HM II; Abbott) The HM II is a small axial flow pump that continuously draws blood from the LV apex by the action of a rapidly rotating impeller and returns the blood to the ascending aorta in a nonpulsatile fashion. It has been approved in the

United States as a bridge to transplantation since 2008 and as destination therapy since 2010. Rates of specific common complications are dramatically lower with the HM II than with the previous generation of pulsatile devices, and the durability of the device far exceeds that of the HeartMate I (>10 years, compared with only approximately 18 months). The current rate of successful bridging to transplantation with the HM II is approximately 87%. Chronic anticoagulation to an INR of 2.5 to 3.5 is recommended for all currently available implantable LVADs, but one advantage of the HM II over other current devices appears to be the duration one can be without anticoagulation, which may be helpful if patients tend toward non-compliance.

The Heartware HVAD (Medtronic) is a miniaturized centrifugal flow pump with a magnetically levitated impeller. It was approved as a "bridge to transplantation" in 2012 and for "destination therapy" in 2017. Its small size and intrapericardial site of implantation are advantageous to allow for its use in patients with smaller body surface areas. Successful rates of bridging to transplantation and overall survival with the HVAD are similar to the HM II, but the HVAD appears to be associated with a slightly higher risk of stroke than the HM II.[449,450] It may be that HVAD would be a less desirable choice in uncontrolled hypertensive patients, as MAPs greater than 90 have been associated with an increased risk for stroke during LVAD support.[449]

The HeartMate 3 (Abbott) is a small intrapericardially positioned continuous flow centrifugal pump with a bearingless, magnetically levitated, magnetically driven impeller. With this centrifugal pump, rotational speeds of 3000 to 5000 rpm can produce upwards of 10 LPM of flow. According to the manufacturer, and as described in the first reported implant in a human,[451] the hemocompatibility of the device was improved through coating of all blood surfaces with the classic HeartMate sintered-titanium microsphere lining. In addition, the risk of thrombosis was reduced by creating three separate flow paths through the device to continuously wash all internal device elements. As well, magnetic levitation of the rotor obviates the need for a bearing, which not only reduces wear-and-tear, but decreases the amount of heat produced during impeller rotation. As has been shown to be advantageous with other "maglev" devices, less heat means less hemolysis, with less resultant plugging of the microvasculature from free hemoglobin in the plasma. In addition, small size and intrapericardial site of implantation allow its use in patients with smaller body surface areas, as with the HVAD.

As overall survival has improved over the past decade, analyses now focus on other details of importance, and the issue of "centrifugal versus axial" design has become an important one. The HM3 was compared to the HM II in the MOMENTUM 3 trial (Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy with HeartMate 3).[452] The first analysis of this key multicenter trial of nearly 300 patients demonstrated a significantly higher rate of a composite endpoint of survival free from either disabling stroke or reoperation for device malfunction at 6 months with the HM3 compared to the HMII (86.2% vs. 76.8%; $P < .001$ for non-inferiority; $P = .04$ for superiority). There were **NO** suspected or confirmed pump thromboses in HM3 patients at 6 months compared to 10.1% of patients implanted with the HMII. Importantly, there were also no significant differences detected between the two groups in the rates of stroke; bleeding; sepsis; RV failure; hepatic, renal, or pulmonary failure; hospital length of stay; rate of discharge from the hospital; arrhythmias; hemolysis; or drive-line infections. Thus, the overall conclusion was that implantation with the HM3 resulted in better outcomes, mainly as a result of fewer reoperations for pump "malfunction." Two-year follow-up data from MOMENTUM 3 was published in 2018,[453] and again, the HM3 was found to be not only "noninferior" to the HM II, but frankly "superior." Regardless of the indication for implantation (bridge to transplantation vs. destination therapy), at 2 years following implantation, 79.5% of those implanted with the HM3 demonstrated survival free from either disabling stroke or reoperation for device malfunction compared to 60.2% of those implanted with the HM II ($P < .001$ for noninferiority and $P < .001$ for superiority). Driving the finding was again freedom from reoperation for pump malfunction (1.6% in the centrifugal-flow pump group vs. 17.0% in the axial-flow pump group $P < .001$). The rates of death and disabling stroke were similar in the two groups, but the overall rate of stroke was lower in the centrifugal-flow pump group than in the axial-flow pump group (10.1% vs. 19.2%; $P = .02$). The HM 3 received FDA approval for "short-term indications" (e.g., "bridge to transplantation") in 2017, and approval for "long-term" indications (e.g., "destination therapy") is anticipated but still pending at the time of this writing.

The CardioWest total artificial heart (TAH-t, SynCardia Systems, Inc, Tucson, AZ) is FDA approved (and approved and available in Europe and Canada) as a bridge to transplantation for patients requiring biventricular long-term support. Two sizes are available: 70 mL ventricles (for patients with a body surface area >1.7 m^2 and an intrathoracic anteroposterior diameter >10 cm at the level of the 10th vertebral level), and 50 mL ventricles (for patients with body surface area <1.7 m^2). Indications for the TAH include: irreversible biventricular failure, allograft failure (rejection or heart transplant vasculopathy), failure to wean from ECMO, massive MI that affects technical insertion of a VAD, recurrent ventricular tachycardia/fibrillation, intracardiac thrombus, tumor, restrictive cardiomyopathy, post infarction VSD, type A aortic dissection with coronary artery dissection, or end-stage congenital heart disease (CHD).[454-456] Survival rates at 3 and 6 months after TAH implantation were reported in 2016 as 76% and 65%, respectively, and 45% of TAH patients from 2005 to 2015 were transplanted by 6 months.[457] Recently, the TAH-t has seen renewed popularity, mainly because it is the only implantable intermediate- to long-term support solution for patients with biventricular failure that is currently available. In previous years, the TAH-t was reported to enjoy a 79% successful rate of bridging patients to transplantation, but no recent data is published in this regard. According to the manufacturer, more than 1100 TAH-t devices have been implanted.

CARDIOMYOPATHIES

Current understanding(s) and classification(s) of "cardiomyopathies" have changed dramatically since the 1980

WHO/ISFC task force definition as "heart muscle diseases of *unknown* cause" and a classification that simply included:

- Dilated cardiomyopathy
- Hypertrophic cardiomyopathy
- Restrictive cardiomyopathy

That same task force document[458] defined heart muscle diseases of *known* cause or associated with disorders of other systems as "specific heart muscle diseases" that included a wide variety of infective diseases, metabolic disorders, generalized systemic diseases (e.g., infiltrative and connective tissue disorders), heredofamilial diseases (e.g., muscular dystrophies), sensitivities, and toxic reactions.

By 2006, significant advances in molecular genetics afforded entirely new understandings of the etiologies and pathogenesis of "heart muscle diseases" such that an entirely new definition and classification of cardiomyopathies was proposed. According to the American Heart Association's 2006 Scientific Statement[459]:

> *"Cardiomyopathies are a heterogenous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive HF-related disability."*

> *"Cardiomyopathies…are not… a direct consequence of other cardiovascular abnormalities such as which occurs with valvular disease, systemic hypertension, CHD, and atherosclerotic coronary artery disease producing ischemic myocardial damage secondary to impairment in coronary flow."*

Thus the current conception of cardiomyopathies classifies them as either primary (a disease confined to the heart) or secondary (cardiac pathology/pathophysiology results as a manifestation of a systemic condition). Primary cardiomyopathies are further subcategorized into genetic, acquired, or mixed in their etiology. Secondary causes of cardiomyopathy are classified by the pathogenesis, and include a wide variety of infectious, endocrine, infiltrative, autoimmune/inflammatory, nutritional, toxic, and neuromuscular diseases. Box 54.16[460] lists examples of the primary cardiomyopathies. In the current conception, acquired (non-genetic) cardiomyopathies are distinguished from secondary cardiomyopathies (e.g., the myocardial dysfunction that results from ischemic coronary disease is no longer considered a "cardiomyopathy").

Distinct from the classification of cardiomyopathies for medical purposes, and regardless of whether the cardiac dysfunction is now called primary or secondary, acquired or inherited, the surgical management of "cardiomyopathy" derives directly from the resultant cardiac pathophysiology. Some cardiomyopathies are amenable to surgical interventions, and some are "managed" with electrophysiological procedural interventions, with or without pharmacological therapies; some require all of these.

Given the acute and potentially severe cardiac mechanical dysfunction associated with several of the primary cardiomyopathies (e.g., peripartum, Takotsubo, myocarditis), urgent MCS or ECMO may be required as a "bridge to immediate survival," a "bridge to next decision," a "bridge to recovery," or a "bridge to a bridge." The majority of the secondary cardiomyopathies and some of the primary ones (e.g., LV noncompaction and dilated) are progressive in nature from the time of their onset. Aside from acute decompensation, they are managed on a long-term basis with either eventual planned cardiac transplantation, or intermediate- and long-term MCS as a "bridge to transplantation," a "bridge to candidacy" (for transplantation), and in some cases, "destination therapy."

Many of the cardiomyopathies associated primarily with electrical dysfunction (but otherwise histiologically normal myocardium) are managed with electrophysiologic procedural interventions (e.g., implantable defibrillators [ICDs], catheter-based percutaneous ablations, cardiac resynchronization therapy with biventricular pacing, etc.).

BOX 54.16 Primary Cardiomyopathies

Genetic

- Hypertrophic
- Ion channelopathies
- Arrhythmogenic RV dysplasia
- LV noncompaction
- Mitochondrial myopathies

Acquired

- Peripartum
- Stress (Takotsubo)
- Myocarditis
- Tachymyopathy

Mixed

- Restrictive
- Dilated

LV, Left ventricular; *RV*, right ventricle.

Adapted from Brieler J, Breeden MA, Tucker J. Cardiomyopathy: an overview. *Am Fam Phys*. 2017;96(10):640–647.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is of autosomal dominant genetic inheritance, and is reported to be the most common primary cardiomyopathy, with a prevalence of 1:500 people.[461] HCM is eminently amenable to both surgical and procedural interventions. Though there are a few described variants, in the most common form, asymmetric interventricular septal hypertrophy can result in ventricular arrhythmias, and (often) SAM of the mitral valve, in which systolic LVOT obstruction can occur; the entity is then called hypertrophic *obstructive* cardiomyopathy, or HOCM. Both arrhythmias and SAM present the risk of sudden death. Thus ICDs and surgical interventions (e.g., septal myectomy, mitral valve repair, release of papillary muscles, etc.) can mitigate both the risk of sudden death and symptomatology. In patients deemed too high-risk for surgery, percutaneous septal alcohol injection can be used to ablate the hypertrophied septal tissue.

Patients with HCM/HOCM should be evaluated regarding their risk of sudden death and the implantation of an ICD.[462] In addition to the potentially protective effects of an ICD, surgical septal myectomy is the treatment of choice for HOCM in patients with interventricular septal thickness greater than 15 mm and/or SAM-prone MV anatomy, but the resection of septal tissue alone is not always sufficient to ameliorate the LVOT obstruction. Adjunctive procedures often need to be performed on the mitral valve and subvalvular apparatus to effect a complete repair. The majority of the patients with LVOT obstruction and associated anomalies of the MV apparatus can be corrected with MV repair without the need for MV replacement.

Potential surgical procedures include:

1. The Morrow myectomy: a classic subaortic septal resection, which is not as commonly performed. The subaortic area is easily accessible for resection but is not always the area causing the SAM.[463]
2. Extended myectomy: more commonly performed in the modern era; the hypertrophied septal myocardium is resected to a point beyond that of mitral-septal contact, usually to the base of the anterolateral papillary muscle, as such resection redirects flow medially and anteriorly away from the mitral leaflets to ameliorate SAM.[464]
3. Papillary muscle release: dividing connections between the papillary muscles and the LV free wall. With release, the mitral apparatus drops posteriorly into the LV, better separating the inflow and outflow portions of the LV, to ameliorate SAM.[465,466]
4. AML plication: to shorten the redundant anterior leaflet and reduce leaflet slack that predisposes to SAM.[467]

Transthoracic echocardiography (TTE) is generally used at the time of initial presentation to verify the location and extent of the disease process and suitability for surgical repair, but TEE is generally used in the operating room. Prior to surgery, TEE is used to assess the location and degree of septal thickness, the presence of SAM-prone anatomy, coexisting mitral regurgitation of primary etiology, associated abnormalities of the mitral apparatus, and quantitation of the gradient across the LVOT. For the best possible outcome, it is important for the echocardiographer to review and discuss ALL TEE findings with the surgeon before instituting CPB, before separating from CPB, and again after final separation from CPB.

Following surgical intervention, it is especially critical for the echocardiographer to understand the specific surgical procedure(s) performed, as this will allow for a more complete assessment of the effectiveness of the intervention. The post-intervention TEE assessment should include:

- the effectiveness of the intervention, sometimes by employing provocative maneuvers to determine if continued obstruction can be elicited,
  - the mitral valve, the chordae tendineae, and the papillary muscles (which may also have been thinned, plicated, resected, and/or released as part of the repair) and,
  - evaluation for potential surgical complications of the myectomy (e.g., VSD, lacerated septal perforator(s)).

Postoperatively the magnitude of the gradient across the LVOT is critically dependent on optimization of preload, afterload, heart rate, and contractility, and whether or not there is still SAM. Initial postbypass gradients often disappear once the patient is optimized and there is no SAM. Factors known to promote SAM include: hypovolemia, vasodilatation, a high contractile state, and tachycardia. One should not attempt to interpret residual gradients until the determinants of hemodynamics more closely mimic the awake state and the patient is rendered normovolemic postoperatively. Residual LVOT gradients between 10 and 30 mm Hg without SAM may be considered acceptable but should prompt consideration of a provocative maneuver to see if it increases. Residual LVOT gradients between 30 and 50 mm Hg and no SAM suggest that the myectomy may be inadequate. Gradients of this magnitude with SAM suggest that hemodynamic optimization may not yet have been realized, and/or that additional repairs of the mitral valve and/or subvalvular apparatus might be needed. A residual LVOT gradient greater than 50 mm Hg due to SAM suggests that further repair of the mitral valve (leaflets, annulus, and/or subvalvular apparatus) may be necessary. If the surgeon has already performed the valve "repair" in addition to the myectomy, this should likely prompt a discussion of possible mitral valve replacement or Alfieri stitch to control the SAM.

Provocative maneuvers that can be used to try to elicit LVOT residual obstruction are not always necessary, but include Valsalva maneuver, reduction in preload (e.g., reverse Trendelenburg position, bolus of NTG, etc.), pharmacological vasodilatation, and/or increase in inotropic state.

An iatrogenic VSD (with flow from left to right ventricles) should be excluded following myectomy, as such will require immediate repair. It is also important, however, to distinguish a VSD from a severed septal branch of the coronary artery anatomy (a coronary-cameral fistula). Such fistulae will demonstrate diastolic flow at the site of the myectomy into the LV. Large severed perforator branches may require ligation or occlusion lest the intracardiac shunt contribute to volume overload and potential cardiac failure.

Historically, such fistulae have generally been reported to be "rare," but the identification of such fistulae is a common echocardiographic finding of which studies report a prevalence in the range of 19% to 23% following myectomy.[468,469] The clinical significance of these fistulae depends on their size (most are trivial), and the natural history is that most spontaneously close within a few weeks. Though one study of 40 myectomy patients in the modern era found that nearly onequarter of such fistulae were still detectable by echocardiography at 6 months postoperatively.[469]

Cardiac Transplantation

Discovery of the immunosuppressive agent cyclosporine in the early 1980s made cardiac transplantation an accepted surgical option for end-stage HF.[470] Currently, 1-year survival is in the range of 80% to 90%, and 5-year survival is approximately 70%.[444] Patients 30 to 59 years old tend to have the best survival, as do recipients who required transplantation because of nonischemic cardiomyopathy. Patients who required transplantation due to CHD and those receiving a retransplant have a reported 1-year survival of approximately 68%.[471]

Most candidates for cardiac transplantation have class D HF that has been maximally treated medically but is nevertheless likely to result in death in less than 1 year. Such patients typically are in cardiogenic shock or have a chronic low-output state that necessitates mechanical or inotropic support, but candidates also include patients with advanced symptomatic HF and peak oxygen uptake less than 10 mL/kg/min (with the achievement of an anaerobic threshold), patients with NYHA class IV HF caused by advanced hypertrophic or restrictive cardiomyopathy, patients with refractory angina pectoris and inoperable CAD, and patients with life-threatening ventricular arrhythmias that are refractory to all appropriate medical and surgical treatment. Usually, the patient's EF is less than 20%. However, patients with NYHA class III HF who are at risk for sudden death related to malignant arrhythmias are sometimes placed on the waiting list.

In the United States, cardiac transplantation is performed in member centers of the United Network for Organ Sharing (UNOS), an umbrella organization responsible for coordinating organ procurement, organ allocation, and statistical information. UNOS allocates donor hearts according to each patient's priority status, ABO group compatibility, body size match, and distance from the donor center. The highest priority is given to inpatients supported by mechanical circulatory assist devices for acute hemodynamic decompensation, patients maintained on assist devices who have significant device-related complications, patients requiring continuous infusion of single or multiple high-dose intravenous inotropic medications, and patients with a life expectancy of less than 7 days without transplantation.

The most common diagnoses in adult patients with HF who require cardiac transplantation include idiopathic or ischemic cardiomyopathy and complex CHD. Less common diagnoses include viral cardiomyopathy, postpartum cardiomyopathy, refractory valvular disease, primary myocardial diseases (e.g., sarcoidosis, amyloidosis), and drug-induced myocardial disease.

The first most common indication is idiopathic dilated cardiomyopathy, which accounted for approximately 46% of all cases in 2018.[471] Worldwide, ischemic cardiomyopathy is now the second most common indication for heart transplantation, accounting for 38% of all registered cases.[444] Similar to the U.S. experience, nonischemic cardiomyopathy has been the most common indication worldwide, accounting for 53% of all registered cases.

The selection criteria have been broadened for both heart recipients and heart donors.[472] For example, patients with diabetes and those older than 65 years old are now considered transplantation candidates in many centers, though they were previously considered exclusion criteria.[473] In addition, although centers generally prefer donors to be younger than 35 years old, the age criterion has been expanded to include suitable donors (e.g., those without cardiac risk factors or evidence of CAD) who are 60 years old or older. Suitability involves the absence of CAD or of major cardiac risk factors for CAD. Major contraindications to heart transplantation that continue to steer patients toward destination therapy with a VAD instead of transplantation include age greater than 70 years, chronic renal dysfunction, and high body mass index.[447] Modifiable risk factors (e.g., pulmonary hypertension) remain the subject of ongoing clinical investigation. Classically, a PVR greater than 5 dyne•s•cm^{-5} unresponsive to pulmonary vasodilators is a relative contraindication, as it indicates a "fixed" PVR, and has been associated with an increased risk for early mortality after orthotopic heart transplantation.[473] Significant issues of non-compliance, lack of a social support structure, comorbidities with a poor prognosis, and significant drug and/or alcohol abuse may also render a patient ineligible for transplantation.

The manner in which the donor heart is implanted has also changed, with a shift away from the classic biatrial technique (originally described by Lower and Shumway in 1960) to the bicaval Wythenshawe technique described in the early 1990s. The advantages of a bicaval implantation technique include lower incidences of LA dilatation, diuretic use, atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and RV failure. In addition, this technique has been demonstrated to be associated with shorter hospital stays. Furthermore, several series that compared the classic Shumway technique with the bicaval technique showed greater 12-month survival in the bicaval group.[474,475]

An even more recent implantation technique further reduces the size of the native LA remnant to two islands containing the pulmonary veins on either side. This so-called "total" technique was described by Dreyfus and Carpentier in 1991.[476]

Because the recipient sinoatrial node is no longer routinely retained with either of the modern bicaval techniques, the concept of two P waves on the posttransplant ECG is now only of historical interest. Posttransplantation physiology, however, remains unchanged: the requisite denervation of the donor organ during harvesting results in the absence of both direct afferent and efferent neural innervation via autonomic or somatic neural pathways after implantation. In plain English, the transplanted heart functions in isolation from the recipient's nervous system, although the potential for direct activation of myocardial receptors (e.g., myocardial adrenergic receptors) by circulating factors is retained, as are all intrinsic myocardial reflexes (e.g., the Starling mechanism, the Anrep effect, the Bowditch effect). The loss of parasympathetic tone in the transplanted heart means that the resting heart rate is faster than normal, and heart rates of approximately 90 to 110 beats/min are usual and often necessary to maintain CO.

A clear understanding of what remains intact and what is lost in the transplanted heart dictates and guides posttransplant anesthetic management. Adequate preload is critical. Direct-acting drugs (e.g., epinephrine, isoproterenol) and pacing are maximally and immediately effective when needed to increase inotropy or chronotropy, respectively, in the transplanted heart. Indirect-acting drugs (e.g., ephedrine, dopamine) rely primarily on the release of epinephrine and norepinephrine from the adrenal glands. Digoxin retains its direct inotropic effect on the heart through inhibition of sodium-potassium adenosine triphosphatase, with resultant buildup of intramyocardial calcium, but loses its potential to decrease chronotropy (a parasympathetically mediated effect on the AV node). One should not expect a decrease or increase in heart rate after the administration of medications that cause bradycardia (e.g., fentanyl) or tachycardia (e.g., meperidine, pancuronium) as a side effect since these side effects work through neural mechanisms. Anticholinergic medications (e.g., atropine, glycopyrrolate) are not expected to increase heart rate in the denervated heart but are always administered at the time of reversal of muscle relaxation by acetylcholinesterase inhibitors to reduce the adverse *extracardiac* cholinergic effects of the anticholinesterase drugs.

The denervated heart is subject to accelerated atherosclerotic disease, causing a significant 5-year incidence of CAD in transplant recipients, but these recipients do not experience angina. Significant dysrhythmias or arrhythmias in a transplanted heart should be considered harbingers of ischemia until proven otherwise.

CONGENITAL HEART DISEASE IN ADULTS

Background and Current Perspective

Medical and surgical advances in CHD surgery since the 1960s have significantly reduced the death rates of patients with CHD. Today, 85% to 95% of babies born with CHD can reach adulthood, and the number of adults with CHD now exceeds the number of children with CHD.[477] Currently there is no formal database of adults with CHD but this population is increasing at a rate of more than 5% annually. Adult patients who present with CHD can have extremely complex conditions that require careful assessment and operative planning. They may present for cardiac surgery for the first time or for further palliative correction, either definitively or for residua. Most patients with CHD face a lifetime of significant challenges,[478] ranging from the complications of long-term antibiotic prophylaxis to thromboembolic ventricular dysfunction resulting from cardiac arrhythmias and pulmonary hypertension.

Preoperative Anesthetic Considerations

The unique problems of this population include the multisystem effects of single-ventricle physiology, cyanosis, systemic right ventricle, complex intracardiac baffles, and failing subpulmonary right ventricle.[477] The initial assessment, history taking, and physical examination of an adult patient with CHD must be broadly systemic to capture any noncardiac organ involvement. A full review of each organ system is beyond the scope of this chapter, but readers are referred to the excellent review articles by Chassot and Bettex[478] and by Lovell.[479] Appropriate consultation with the patient's cardiologist (pediatric or adult), as well as access to old medical records, is valuable, especially for patients who have complex CHD or have undergone complex surgical procedures. Preoperative echocardiography is extremely helpful in understanding the anatomy and the primary and compensatory cardiac function of patients with CHD.

One of the early clinical decisions to be made for an individual patient involves determining the appropriateness of surgical care in a given institution. Obviously, emergency procedures give very little latitude, but elective procedures should warrant careful assessment, especially of the abilities and experience of the anesthesiologist who will be caring for a patient with complex corrected or palliated CHD. In 2001, the Thirty-second Bethesda Conference on CHD advocated the creation of regional centers for the care of adults with CHD (ACHD centers), whose personnel would include a cardiac anesthesiologist and other subspecialists with expertise in the management of patients with CHD.[480] The conference recommended that all adult patients with complex (Box 54.17) and moderate (Box 54.18) CHD be referred to such ACHD centers. Current U.S.[481,482] and Canadian[477] updates to these guidelines continue to support these recommendations.

BOX 54.17 **Types of Adult Congenital Heart Disease of Great Complexity**

Conduits, valved or nonvalved
Cyanotic congenital heart disease (all forms)
Double-outlet ventricle
Eisenmenger syndrome
Fontan procedure
Mitral atresia
Single ventricle (also called double inlet or outlet, common, or primitive)
Pulmonary atresia (all forms)
Pulmonary vascular obstructive disease
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus or hemitruncus
Other abnormalities of atrioventricular or ventriculoarterial connection not included here (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

From Warnes CA, Williams RG, Bashore TM, et al. ACC/AHA 2008 guidelines for the management of adults with congenital heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Adults with Congenital Heart Disease). Developed in collaboration with the American Society of Echocardiography, Heart Rhythm Society, Angiography and Interventions and Society of Thoracic Surgeons. *Circulation*. 2008;118:2395–2451.

Intraoperative Anesthetic Considerations

Discussion of specific anesthetic management techniques for particular congenital heart defects in adult patients is not within the scope of this chapter. However, a few basic principles are essential for all anesthesiologists to know, especially those who do not have specialized training in cardiac anesthesia or CHD but who may be faced with an older patient with CHD who needs urgent noncardiac surgery.

Preparation of the anesthetic plan requires detailed knowledge of the anatomy and physiology of the lesion.[479] A skilled multidisciplinary team is very helpful for providing optimal management.[483,484] During the preoperative assessment of an adult with CHD, an extensive review should be conducted to elicit signs of CHF, cyanosis, or compromised peripheral vascular disease. Anesthetic considerations are lesion specific and are discussed in several reviews.[479,485,486]

Principle 1: The Presence or Absence of Cyanosis. Cyanosis is usually a marker for complex CHD. Chronic cyanosis can lead to the development of abnormalities of RBC production and hemostasis. Elevated levels of erythropoietin in cyanotic patients can lead to a hyperviscosity syndrome and increased risk of neurologic injury.

In any patient with cyanotic CHD, the anesthesiologist should establish intravenous fluid therapy and monitor

BOX 54.18 Diagnoses in Adult Patients With Congenital Heart Disease of Moderate Complexity

Anomalous pulmonary venous drainage, partial or total
Aorto–left ventricular fistula
Atrioventricular septal defect (partial or complete)
Coarctation of the aorta
Ebstein anomaly
Infundibular right ventricular outflow obstruction of significance
Ostium primum atrial septal defect
Patent ductus arteriosus (not closed)
Pulmonary valve regurgitation (moderate to severe)
Pulmonary valve stenosis (moderate to severe)
Sinus of Valsalva fistula or aneurysm
Sinus venosus atrial septal defect
Subvalvular or supravalvular aortic stenosis (except HOCM)
Tetralogy of Fallot
Ventricular septal defect with:
  Absent valve or valves
  Aortic regurgitation
  Coarctation of the aorta
  Mitral valve disease
  Right ventricular outflow tract obstruction
  Straddling tricuspid or mitral valve
  Subaortic stenosis

HOCM, Hypertrophic obstructive cardiomyopathy.
From Warnes CA, Williams RG, Bashore TM, et al. ACC/AHA 2008 guidelines for the management of adults with congenital heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Adults with Congenital Heart Disease). Developed in collaboration with the American Society of Echocardiography, Heart Rhythm Society, Angiography and Interventions, and Society of Thoracic Surgeons. *Circulation.* 2008;118:2395–2451.

urine output to overcome the adverse circulatory effects of perioperative fasting, dehydration, and intraoperative hypovolemia. These conditions cause hyperviscosity, which can be associated with hemostatic abnormalities. Many patients with congenital repairs that include a conduit or graft are maintained on antiplatelet medications, and this should be noted. Arterial pressure monitoring may be prudent, and the decision to place a central venous catheter should be made in careful consideration of the patient's anatomy and proposed surgical repair.

Principle 2: The Presence or Absence of Intracardiac or Extracardiac Shunts. Intracardiac shunts are classically located at the level of the atria or ventricles. The magnitude of the shunt is often expressed in terms of the ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs): Qp/Qs. Balanced flow, or a ratio equal to 1, is the hallmark of normal physiology. A Qp/Qs ratio greater than 1 is generally consistent with acyanotic heart disease and luxuriant pulmonary blood flow. A Qp/Qs ratio less than 1 would be consistent with cyanosis. Intracardiac shunts and the Qp/Qs are often bidirectional, depending on situational physiology, and therefore must always be considered to be a risk for systemic embolization. The location and size of intracardiac shunts are critically important to the management of anesthesia care for patients with CHD.[478] The direction and magnitude of flow across an intracardiac or extracardiac shunt is directly related to the balance between PVR and SVR, a relationship that can be managed by vasoactive agent administration.

1. The direction of shunt flow is important. Shunts can be right, left, or bidirectional. Shunt flow can be influenced by changes in driving pressure across a shunt or pressure in the receiving chamber. The high intrathoracic pressure that can occur with mechanical ventilation, coughing, the Valsalva maneuver, bronchospasm, or positive end-expiratory pressure can actually reverse the direction of a left-to-right shunt or at least make it bidirectional. Therefore, paradoxical embolization by clot or air is a real risk in patients with intracardiac shunts and warrants fastidious attention to de-airing intravenous lines and careful administration of drugs by syringes through ports in intravenous lines.
2. The size of the intracardiac defect is important. Shunts are commonly labeled as restrictive or nonrestrictive according to their blood velocity or pressure characteristics measured at catheterization or by echocardiography. Large defects with associated low-pressure gradients across them have nonrestrictive flow. In addition, larger defects can be expected to have a greater effect on downstream structures and pressures. Small defects with high pressure or gradients restrict the amount of blood flow. The mainstays of the anesthetic management of shunt lesions are understanding and controlling factors that may influence the direction and magnitude of the shunt. Shunt flow and direction are directly influenced by both PVR and SVR. Elevated SVR and decreased PVR generally increase the magnitude of left-to-right shunting. Conversely, decreased SVR and/or increased PVR decrease the magnitude of left-to-right shunting, or will create a right-to-left shunt. Mechanical ventilation, the inspired oxygen concentration, carbon dioxide levels, and the hemodynamic effects of anesthetic drugs are all used to achieve certain therapeutic goals in relation to PVR and SVR, and hence, shunt management. Oxygen is a potent pulmonary vasodilator, as is hypocapnia. If the clinical problem is luxuriant pulmonary blood flow, a high FiO_2 should be avoided. Similarly, the direction and magnitude of the shunt flow determine whether one should hyperventilate a patient to achieve a low $Paco_2$ or tolerate a high-normal $Paco_2$.
3. In the presence of a shunt, the potential dilation of the cardiac chambers and resultant increase in chamber volume and pressure are important. A shunt above the level of the AV valves, such as a left-to-right shunt at the atrial level, usually causes right-sided chamber enlargement. Left-to-right shunts at any level that increase pulmonary blood flow can lead to elevations in PVR and pulmonary arterial pressure. Furthermore, exposure to elevated pulmonary pressure and afterload leads to continued right heart enlargement, RV failure, bidirectional shunting, and in extreme cases, a reversal of shunt direction, or right-to-left shunting. Clinically this manifests as cyanosis. When PVR becomes elevated, fixed, and irreversible, this is referred to as Eisenmenger syndrome.

Extracardiac shunts can be native to CHD (e.g., aberrant pulmonary venous return), surgically created (e.g., Blalock-Taussig shunt), or compensatory (e.g., aortopulmonary collateral formation with long-standing cyanotic heart disease). Special mention of certain aortopulmonary shunts, used commonly in the past to palliate some forms of cyanotic heart disease, is warranted. The proximal connection may be to the ascending aorta, brachiocephalic trunk, or subclavian artery. Because blood flow through this type of shunt is dependent on systemic blood pressure, systemic hypotension may lead to worsening hypoxemia. Furthermore, long-term exposure to these extracardiac shunts can result in left-sided chamber enlargement and dysfunction secondary to chronic volume overload.

Principle 3: The Presence of Pulmonary Hypertension. Pulmonary arterial hypertension is defined as a mean PAP greater than 25 mm Hg or greater than 30 mm Hg with exercise. Some degree of pulmonary hypertension develops in 5% to 10% of adult patients with CHD. This is associated with exercise intolerance and decreased functional capacity, which appear to have important prognostic implications.[484]

The anesthetic management of patients with pulmonary hypertension can be challenging. Invasive monitoring and careful anesthetic titration may be required. Regional anesthesia may be used for appropriate procedures, but neuraxial blocks should be administered with caution because of the sympathetic blockade produced. Patients with significant pulmonary hypertension are very sensitive to preload; therefore, hypovolemia, should be treated immediately and aggressively. Pulmonary hypertension can be managed pharmacologically and mechanically. Factors associated with decreasing PVR and, subsequently, reductions in PAP are listed in Box 54.19.[479]

BOX 54.19 Factors Associated With Decreasing Pulmonary Vascular Resistance and Reductions in Pulmonary Artery Pressure

Decrease in Pulmonary Vascular Resistance

- Increasing PaO_2
- Hypocapnia
- Alkalemia
- Minimizing intrathoracic pressure
  - Spontaneous ventilation
  - Normal lung volumes
  - High-frequency and jet ventilation
  - Avoidance of sympathetic stimulation
  - Deep anesthesia
- Pharmacologic methods
  - Isoproterenol
  - Phosphodiesterase III inhibitors
  - Prostaglandin infusion (PGE_1 and PGI_2)
  - Inhaled nitric oxide

Increase in Pulmonary Vascular Resistance

- Sympathetic stimulation
  - Light anesthesia
  - Pain
- Acidemia
- Hypoxia
- Hypercapnia
- Hypothermia
- Increased intrathoracic pressure
  - Controlled ventilation
  - Positive end-expiratory pressure
  - Atelectasis

PaO_2, Partial pressure of arterial oxygen; *PGI_2*, prostacyclin.

From Lovell AT. Anaesthetic implications of grown-up congenital heart disease. *Br J Anaesth.* 2004;93:129–139.

Principle 4: The Presence of Ventricular Dysfunction. As in adult patients with acquired heart disease, the presence of ventricular dysfunction is an important risk factor for morbidity and mortality, both in the perioperative period and in the long term. Regarding RV dysfunction, predictors of a poor outcome may include pulmonary hypertension, pulmonic valve incompetence, and consequent dysfunction of the subpulmonic ventricle.[486] LV dysfunction has been observed after repair of tetralogy of Fallot in the adult. Risk factors associated with this dysfunction include male gender, LV enlargement, duration of shunt before repair, history of arrhythmia, long QRS duration, presence of an ICD, and moderate-to-severe RV dysfunction preoperatively.[487]

OTHER CARDIAC PROCEDURES

Surgical Ablation of Atrial Fibrillation

In the United States, 2.7 to 6.1 million persons are estimated to have atrial fibrillation.[488] Among Medicare patients 65 years old or older, the prevalence of atrial fibrillation increased from 3.2% in 1992 to 6.0% in 2002 and is higher in older patients.[489] Stroke remains the most feared complication of atrial fibrillation; stroke risk is fourfold to fivefold higher in patients with atrial fibrillation than in patients without this arrhythmia. Additionally, atrial fibrillation causes 24% of strokes in patients older than 80 years old.[488]

With regard to persistent atrial fibrillation, both the left atrium and the pulmonary veins have been implicated in the pathogenesis and maintenance of persistent atrial fibrillation. Paroxysmal atrial fibrillation, conversely, may result from the juxtaposition of the pulmonary vein endothelium and the LA endocardium. The transition of the electrical signal from one type of tissue to the other is probably responsible for this arrhythmia.

The classic Maze procedure is currently the most effective curative therapy for atrial fibrillation.[490,491] To simplify the procedure and improve its results, Cox and colleagues modified the operation twice, hence its current name, the Cox-Maze III procedure.[490] This procedure appears to cure atrial fibrillation in 99% of cases.[491] Current indications for the Cox-Maze III operation include drug intolerance, arrhythmia intolerance, and recurrent embolic events.[492]

Ablative treatments for atrial fibrillation involve making RA and LA incisions and cryolesions to interrupt the multiple reentrant circuits that cause atrial fibrillation. Isolating the pulmonary veins and excising the LAA are integral parts of the Maze procedure, which requires CPB and cardiac standstill using cardioplegia.[493-495] This procedure can be performed through a minimally invasive chest incision, as an alternative to sternotomy, while the patient is undergoing CPB.

A study done by Prasad and co-workers found that the Cox-Maze III procedure effectively cured atrial fibrillation when the operation was performed alone or concomitantly with coronary or valve procedures.[492] In patients who underwent such concomitant operations, the Cox-Maze III

TABLE 54.21 Energy Sources for Surgical Ablation of Atrial Fibrillation

Energy Type	Endocardial Application	Epicardial Application	Flexible Probe	Assess Transmural	No Char	Rapid
Radiofrequency*	+	+	+	+	–	+
Microwave	+	+	+	–	+	+
Cryothermy	+	+	–	–	+	–

*Radiofrequency energy may be delivered in unipolar or bipolar fashion. A commercially available bipolar instrument allows the operator to assess transmurality.

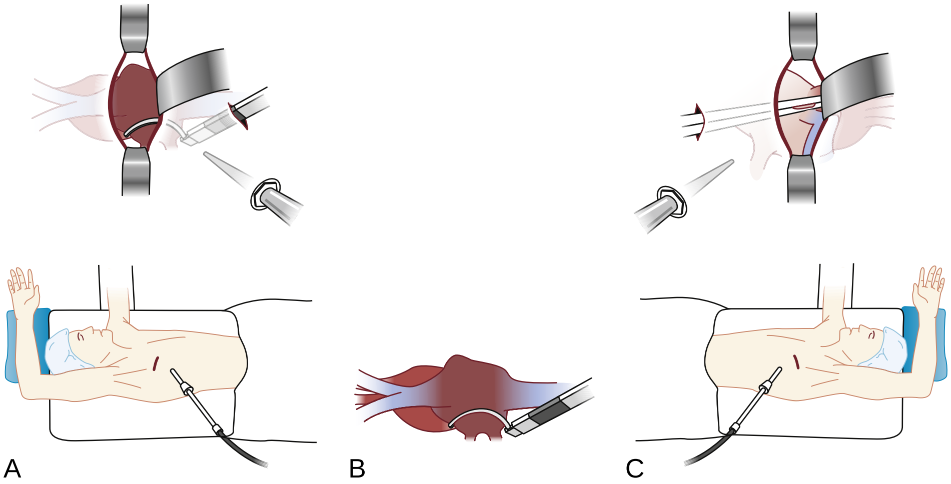

Fig. 54.54 "Keyhole" approach for minimally invasive epicardial pulmonary vein isolation with excision of the left atrial appendage. (A) Access to the right pulmonary veins is gained through a keyhole incision under endoscopic guidance. (B) A bipolar radiofrequency clamp is used to isolate the left atrial cuff adjacent to the right pulmonary veins. (C) Stapled excision of the left atrial appendage after the left pulmonary veins are isolated with a technique similar to that shown for the right pulmonary veins. (From Gillinov AM, Wolf RK. Surgical ablation of atrial fibrillation. *Prog Cardiovasc Dis*. 2005;48:169–177.)

procedure did not significantly add to the mortality or morbidity associated with the revascularization or valve repair procedure.

The underuse of the Maze procedure in the past probably reflected the procedure's perceived complexity. Currently, newer technologies enable the rapid creation of lines of conduction blockade, which surgeons use to ablate atrial fibrillation in patients undergoing concomitant cardiac surgical procedures. These technologies include alternate energy sources such as radiofrequency and microwave energy, ultrasound, cryotherapy, and laser (Table 54.21). These technologies are also used in minimally invasive surgical ablation procedures to cure isolated atrial fibrillation.[491] Furthermore, the development of epicardial probes has facilitated off-pump ablation of atrial fibrillation in the beating heart.

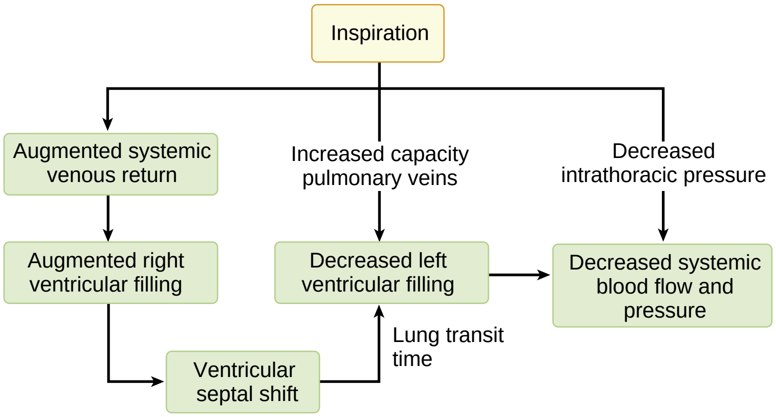
Because cardiac structures can be visualized directly during open surgical procedures, ablation lines can be created safely, thus avoiding the complication of pulmonary vein stenosis. An epicardial approach to ablation eliminates the risk of esophageal injury.[490,491] The advantage of a surgical approach is the ease of excising the LAA, which virtually eliminates the risk of stroke. However, isolation of the pulmonary vein and excision of the LAA can now be done through the minimally invasive "keyhole approach" (Fig. 54.54) or a thoracoscopic approach.[496] Both epicardial approaches can be used without the need for CPB.[491] As experience with the Cox-Maze procedures increases and the technology continues to advance, the goal is to improve patients' quality of life and free them from the need for antiarrhythmic and anticoagulant medications.

Pericardial Tamponade and Constrictive Pericarditis

Pericardial Tamponade. The pericardial sac has two layers: the outer, parietal pericardium; and the inner, visceral pericardium (epicardium), which is directly adherent to the surface of the heart. The normal amount of fluid between the two layers is 15 to 30 mL, which generates a pressure that is 5 mm Hg less than the CVP and approximates the pleural pressure.

Cardiac tamponade occurs when the volume of fluid trapped in the pericardial sac increases and compresses the heart, thereby compromising CO.[497] In classic tamponade, the circulation adapts by increasing the systemic venous and pulmonary venous pressures to equalize with the pericardial pressure so that total collapse of the cardiac chambers is prevented.[498] The PCWP and the LV, RV, and RA diastolic pressures increase to equalize with the pressure in the pericardium. As a result, the atrial and ventricular diastolic transmural pressures are essentially zero, a hallmark of pericardial tamponade. Although this virtual loss of pressure reduces the stroke volume, high adrenergic tone helps to partially preserve CO by increasing the heart rate.

If enough fluid accumulates, the pericardium reaches a stage at which it can no longer distend; therefore, the



Inspiration
Augmented systemic venous return
Increased capacity pulmonary veins
Decreased intrathoracic pressure
Augmented right ventricular filling
Decreased left ventricular filling
Decreased systemic blood flow and pressure
Lung transit time
Ventricular septal shift

Fig. 54.55 Physiology of paradoxical pulses in cardiac tamponade. (From Fowler NO. Diseases of the pericardium. *Curr Probl Cardiol.* 1978;2:6–38.)

total pericardial volume no longer changes throughout the respiratory cycle.[498] This results in a phenomenon referred to as ventricular interdependence, wherein any change in the volume of one side of the heart causes the opposite change in the volume of the other side. During inspiration, increased venous return and filling of the right heart cause the interatrial and interventricular septa to bulge to the left, compromising the ability of the LV to eject. Opposite changes occur during expiration. Such ventricular interdependence is evident on echocardiography.

Ventricular interdependence manifests clinically as pulsus paradoxus,[499] an exaggeration of the normal diminution of the radial pulse on inspiration (Fig. 54.55). *Pulsus paradoxus* is defined as a drop in systolic blood pressure exceeding 10 mm Hg during inspiration.[500] In particularly severe cases, no brachial or radial pulse may be palpable on inspiration.[501]

Cardiac tamponade is not necessary to cause pulsus paradoxus. Wide swings in intrathoracic pressure and conditions such as pulmonary embolism or hypovolemic shock can also give rise to the phenomenon. Additionally, patients with cardiac tamponade may not have pulsus paradoxus if they have coexisting aortic insufficiency, ASD, or preexisting elevated LVEDP resulting from LV hypertrophy or dilatation.

Fig. 54.56 illustrates the pressure-volume relationship in the pericardium, depending on whether the effusion is accumulating slowly or rapidly.[501] This J-shaped curve suggests that a sudden increase in pericardial fluid volume of 100 to 200 mL can increase pericardial pressure to 30 mm Hg or more and cause severe cardiac tamponade. The faster the fluid accumulation, the more severe is the hemodynamic compromise. Causes of this type of acute tamponade include rupture of a thoracic aortic aneurysm, traumatic mediastinal injury, and accidental puncture of a cardiac chamber or blood vessel in the CCL.[498]

When accumulation of pericardial fluid is slower, compliance of the parietal pericardium is greater, and changes in volume produce smaller rises in pressure than they would if fluid accumulated more rapidly. As pericardial volume increases, so does intrapericardial pressure, with a compensatory increase in CVP to maintain a gradient to allow cardiac filling.[497] When pericardial compliance cannot increase further, the intrapericardial pressure gradually equalizes with the pressures in the cardiac chambers.

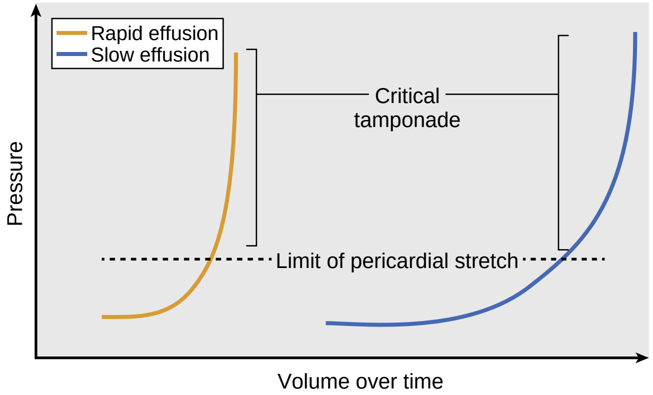


Fig. 54.56 Cardiac tamponade. Pericardial pressure-volume (or strain-stress) curves are shown in which the volume increases slowly or rapidly over time. On the *left,* rapidly increasing pericardial fluid first reaches the limit of the pericardial reserve volume (the initial flat segment) and then quickly exceeds the limit of parietal pericardial stretch, thus causing a steep rise in pressure, which becomes even steeper as smaller increments in fluid cause a disproportionate increase in the pericardial pressure. On the *right,* a slower rate of pericardial filling takes longer to exceed the limit of pericardial stretch because more time is available for the pericardium to stretch and for compensatory mechanisms to become activated. (From Spodick DH. Acute cardiac tamponade. *N Engl J Med.* 2003;349:684–690.)

CO gradually declines, accompanied by a compensatory tachycardia, peripheral vasoconstriction, and increased contractility.

SYMPTOMS AND SIGNS. Patients with pericardial tamponade may present with pain or feelings of fullness in the chest, dyspnea, lethargy, fever, cough, weakness, fatigue, anorexia, or palpitations.[497] The Beck triad may appear as a combination of three signs of severe tamponade: low blood pressure, increased jugular venous pressure, and distant heart sounds. However, patients whose tamponade develops secondary to a chronic medical condition (e.g., malignant disease, end-stage renal disease, collagen vascular disease) may not present with the classic findings of the Beck triad.

ECHOCARDIOGRAPHIC FEATURES OF PERICARDIAL TAMPONADE. Of the various echocardiographic signs of cardiac tamponade (Box 54.20), one of the best established is diastolic collapse of the right atrium or right ventricle. RV collapse, seen in early diastole, appears as an invagination of the RV free wall (Fig. 54.57). In contrast, RA collapse is seen in late diastole and early systole and appears as an invagination of the RA wall (see Fig. 54.57). The timing of the collapse of the two chambers is related to the lowest intracavitary pressures in those chambers (i.e., early diastole for the right ventricle and late diastole to systole for the right atrium). The presence of both RV and RA collapse indicates hemodynamically significant pericardial effusion. Left-sided heart collapse is rarely seen, both because the thickness and stiffness of the LV enable it to resist collapse and because the left atrium is located posteriorly. However, in patients with very large effusions, fluid does accumulate behind the left atrium and eventually collapses this chamber.[502] The presence of LA collapse is highly specific for tamponade.[501]

ANESTHETIC MANAGEMENT OF PERICARDIAL TAMPONADE. Indications for pericardiocentesis (surgical drainage of the pericardial effusion) were summarized by Soler-Soler and co-workers (Box 54.21).[503] Surgical intervention for pericardial disease warrants invasive monitoring, which should involve an intraarterial catheter and possibly a central venous catheter. Large-bore intravenous access should be secured prior to anesthesia induction.

BOX 54.20 Doppler Echocardiographic Signs of Cardiac Tamponade

- Exaggerated inspiratory variation of the two ventricles (inspiratory expansion of the right ventricle and simultaneous compression of the left ventricle; reciprocal changes in the expiratory phase)
- Right atrial collapse
- Right ventricular collapse
- Left atrial collapse
- Left ventricular collapse
- Inferior vena cava plethora
- Abnormal increased respiratory variation in transvalvular blood flow velocities (mitral and aortic flow reduction in the inspiratory phase)

From Pepi M, Muratori M. Echocardiography in the diagnosis and management of pericardial disease. *J Cardiovasc Med (Hagerstown).* 2006;7:533–544.

In patients who are severely hemodynamically compromised, one surgical option is to perform pericardiocentesis or subxiphoid exploration using local anesthesia[504] and inducing general anesthesia after the tamponade has been partially relieved. If general anesthesia is planned, the watchwords in the management of cardiac tamponade are *fast*, *full*, and *strong*. Heart rate should be maintained at a high normal level so as to maintain CO in a stroke-volume-limited ventricle. Intravenous fluids should be administered before induction of anesthesia to optimize preload. Increasing intravascular volume helps to increase the effective filling pressures of the heart, restore the gradient between the chambers, and increase arterial pressure.

Any manipulation that can decrease venous return to the heart should be avoided. This includes controlled positive-pressure ventilation with large tidal volumes, which may significantly decrease preload and CO.[504] If general anesthesia is required, one option is to perform prep and drape to the point of surgical incision and then, after induction of anesthesia, rapidly perform evacuation of the pericardial effusion. Another option is to induce general anesthesia but to allow the patient to breathe spontaneously, avoiding positive intrathoracic pressure, until the pericardial sac is opened.[504] Alternatively, a ventilation pattern of high rate and low tidal volumes can be used to minimize mean airway pressure.

Drugs that may cause myocardial depression should be avoided and thus etomidate is often chosen as the induction agent of choice.[505] Additionally, bradycardia should be avoided because tachycardia is the most important compensatory mechanism for preserving CO. The use of ketamine to induce general anesthesia for creation of a pericardial window has been described.[506]

Once cardiac tamponade is relieved, endogenously generated and exogenously administered catecholamines may cause sudden, severe increases in blood pressure and heart rate. This phenomenon should be anticipated and treated.

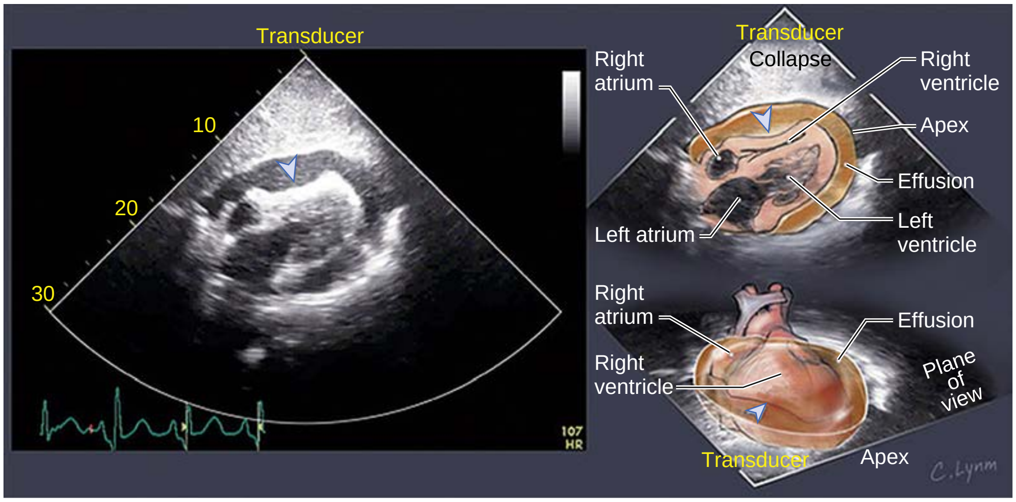

Fig. 54.57 Echocardiogram (and drawings) showing pericardial effusion causing cardiac tamponade. A subcostal view in early diastole shows a large circumferential pericardial effusion compressing the heart, with the right ventricle completely collapsed (*arrowheads*). (From Roy CL, Minor MA, Brookhart MA, et al. Does this patient with a pericardial effusion have cardiac tamponade? *JAMA.* 2007;297:1810–1818.)

Constrictive Pericarditis

Pathophysiology. Constrictive pericarditis is said to be present when the diastolic filling of the heart is restricted by a thickened and adherent pericardium. Several causes of constrictive pericarditis have been identified, including infectious processes. In addition, radiation to the chest area and cardiac surgery itself have emerged as additional causes of constrictive pericarditis over the past few decades.[507] If the two pericardial layers—visceral and parietal—become adherent as a result of fibrosis and calcification of the pericardium, the space between the two layers is obliterated.[507]

Signs and Symptoms. Typically, patients with constrictive pericarditis present with signs and symptoms of right-sided HF. A high driving pressure across the valves causes a rapid filling of the ventricles in diastole and results in sudden increase in the ventricular pressures. As the ventricular pressures exceed the atrial pressures, flow abruptly stops, and pressures are elevated and equalized in all four chambers.[507]

Another sign seen in constrictive pericarditis is the Kussmaul sign (an exaggeration of the x and y descent on the CVP tracing), which is elicited in response to increased blood return to the right side of the heart on inspiration. Because the thickened pericardium no longer allows the heart to expand to accommodate all the blood flowing into it, the pressure generated by this returning volume is transmitted to the central venous system.[508]

As in pericardial tamponade, pulsus paradoxus is also usually seen in constrictive pericarditis. However, in some cases, thickening of the pericardium can shield the myocardium from the effects of the respiratory cycle; therefore, pulsus paradoxus may not be that obvious. Dyspnea and orthopnea are common in patients with constrictive pericarditis because the low CO caused by constrictive pericarditis severely reduces the patient's exercise tolerance and, in extremely advanced cases, causes cardiac cachexia and muscle wasting.[509] Ascites and peripheral edema may also be seen. Echocardiography is particularly helpful in differentiating constrictive pericarditis from other disease processes with similar presenting symptoms, such as restrictive cardiomyopathy.[509,510]

Anesthetic Considerations for Pericardiectomy. The definitive treatment for constrictive pericarditis is pericardiectomy.[511] This procedure is usually performed through a sternotomy, but it can also be performed through a left thoracotomy incision. In patients with severe cases of the disease, pericardiectomy may involve stripping the pericardium off the heart, which may necessitate the use of CPB.

The hemodynamic management of a patient undergoing pericardiectomy for constrictive pericarditis is similar to that of a patient having a surgical intervention for pericardial effusion and tamponade. However, because the pericardium may need to be "peeled" from the surface of the heart, pericardiectomy carries an additional risk of arrhythmia and injury to the myocardium itself, including rupture of one of the chambers. The raw surface of myocardium and the peeling of pericardium cause the release of fibrinolytic activators, and the complement and coagulation cascades are activated. Thus, pericardiectomy can be associated with generalized bleeding due to consumptive coagulopathy, in addition to actual surgical bleeding. Measures should be taken to avoid and treat arrhythmias and massive intraoperative bleeding.

BOX 54.21 Indications for Pericardiocentesis and Surgical Drainage

Pericardiocentesis is indicated in patients with overt clinical tamponade, in patients with suspected purulent pericarditis, and in patients with idiopathic chronic large pericardial effusion.

Indications for surgical drainage are tamponade, either unresolved or relapsing after pericardiocentesis, and persistent active illness 3 weeks after hospital admission.

Pericardial drainage does not seem to be warranted in the initial management of patients with large pericardial effusions without clinical tamponade because of its low diagnostic yield and poor influence on the evolution of pericardial effusion. Even the presence of echocardiographic right chamber collapse (suggesting raised intrapericardial pressure) does not by itself warrant pericardial drainage because most of these patients do not develop overt tamponade.

Modified from Soler-Soler J, Sagrista-Sauleda J, Permanyer-Miralda G. Management of pericardial effusion. *Heart.* 2001;86:235–240.

Cardiac and Aortic Trauma

Penetrating Cardiac Injury. With the increase in violent crime over the past few decades, the number of cases of gunshot and stab wounds to the heart has risen. Patients with penetrating cardiac injury may be critically unstable because of hemorrhage or cardiac tamponade, or they may have a benign injury to the heart.[512] Hemodynamic and ECG changes may be deceptively absent in many cases. The absence of these changes does not rule out the presence of life-threatening injury to the heart or its surrounding structures.[513] Echocardiography can identify fluid or blood around the heart and can inform the surgical decision regarding whether to perform a sternotomy or to use an alternative approach.[512,514]

The anesthetic management of patients with penetrating cardiac injury is similar to that of other trauma patients. Unstable patients require emergency surgical intervention. The anesthesiologist must ascertain that blood is available on first knowledge of impending surgery for penetrating cardiac injury. With critically unstable patients, the anesthesiologist must secure the airway, establish intravenous access, and place the monitoring lines while the surgical incision is being made. An assistant can be very helpful in efficiently caring for such a patient. In planning the induction of anesthesia and the securing of the airway, the anesthesiologist should assume that the patient probably has a full stomach and volume depletion. Monitoring lines should include an arterial line and a central venous catheter. Barring any contraindications, on the basis of the scant history that may be available at that time, TEE should be considered as an additional monitor. Anesthesia management involves attempting to maintain stable hemodynamics and prevent recall. As in any trauma case, if the patient is unstable, controlled postoperative ventilation is usually preferred, including transportation to the ICU with full monitoring and ventilatory support.

Traumatic Aortic Injury. Blunt aortic injury, which can result in either traumatic aortic transection (TAT) or acute rupture, is one of the most common causes of death from blunt trauma, second only to head injury. On arrival at the hospital, only 25% of patients with blunt thoracic trauma and resultant aortic injury (TAT or acute rupture) are alive.[515] Furthermore, the prognosis of patients who survive the initial injury and remain untreated is poor: 30% die within the first 6 hours, 50% die in the first 24 hours, and 90% die within the first 4 months.[516]

In blunt trauma to the chest, the mechanism of injury to the thoracic aorta is sudden traction on the relatively immobile portion of the aorta, the isthmus, as a result of sudden deceleration.[515] The isthmus is distal to the left subclavian artery, proximal to the third intercostal artery, and fixed to the left PA by the ligamentum arteriosum. This area of attachment of the ligamentum arteriosum acts as a hinge for movement of the aortic arch; thus, it receives the brunt of the shearing force during violent injury to the chest area. Hence, it is the most common location for rupture of the aorta (50%-70%), followed by the ascending aorta or the aortic arch in 18% and the distal thoracic aorta in 14% of cases.[515] The spectrum of injuries to the thoracic aorta in blunt thoracic trauma ranges from simple subintimal hemorrhage to complete aortic transection.

The diagnosis of the aortic injury may be made on the basis of a plain chest radiograph, computed tomography, angiography, or TEE. TEE can also detect cardiac tamponade, left pleural effusion, hypovolemia, ventricular dysfunction from myocardial contusion, or vascular injuries from penetrating chest wounds.[517] Diagnosing TAT with TEE requires recognition of a mural flap at the site of intimal disruption and corresponding deformities of the aortic wall caused by a contained rupture. A gap of more than 7 mm between the probe and the aorta at the level of the proximal descending thoracic aorta, in addition to blood between the aortic wall and the pleura, strongly suggests disruption of the aorta. TEE can also be useful in monitoring the progression of a small intimal tear or as a screening tool for patients who have a normal mediastinum after blunt thoracic trauma.

Management of TAT focuses on the high risk of rupture that this injury entails. The unpredictable timing of this event adds to the concerns regarding these patients. Aggressive management of blood pressure in the preoperative period is necessary to minimize the risk of rupture.[518] Systolic blood pressure should not exceed 100 mm Hg, and the heart rate should not exceed 100 beats/min. The use of β-blockers and nitroglycerin or sodium nitroprusside infusions is recommended.

Intraoperative monitoring should include an arterial catheter and central venous access and a large-bore IV should be secured. The keys to anesthetic management of patients with TAT are avoiding wide swings in systolic blood pressure and continuously monitoring the patient for end-organ ischemia. Because many operations on patients with TAT are performed on an emergency basis, it may be necessary to use a modified rapid-sequence induction. Despite all precautions, marked swings in blood pressure are often seen during induction and laryngoscopy. Agents such as nitroglycerin and esmolol should be immediately available to treat any undesirable hypertension during endotracheal intubation, TEE probe insertion, and surgical incision.

Surgical repair of injuries to the ascending aorta or aortic arch typically requires CPB with DHCA. Injuries to the descending thoracic aorta may require open repair of a short segment. Challenges include preservation of vital organs, particularly the spinal cord. In open procedures, use of partial LHB can facilitate the operation and at the same time preserve visceral organ and spinal cord perfusion. This technique also prevents aggravation of any other injuries that the patient may have sustained because this type of bypass does not require large-dose heparin.[516] Although open repair is possible, transcutaneous endovascular aortic repair has emerged as the preferred intervention whenever possible (STS class I recommendation; level of evidence B).[519,520]

Ischemic and Other Emergencies in the Cardiac Catheterization Laboratory

With rapid advances in interventional cardiology, the number of patients in the United States and Europe who undergo interventional therapy in a CCL is increasing. Such emergencies include coronary artery dissection, free rupture, tamponade, foreign body embolism, and wire entrapment. Patients may be at high risk for complications in the CCL if they have unfavorable coronary anatomy or severe ventricular dysfunction. In some cases, cardiac surgery and cardiac anesthesia services should be consulted and placed on standby for a possible emergency intervention. Rapid surgical intervention, such as revascularization or temporary mechanical support, is crucial to reducing the mortality and morbidity of patients who suffer angiography-related accidents.

When ischemic complications occur during cardiac catheterization with percutaneous transluminal coronary angioplasty and stenting, pharmacologic intervention and, possibly, a device such as an IABP or VAD may be used to stabilize the patient's hemodynamic condition before the patient is transferred to the operating room on an urgent or emergency basis for open coronary revascularization. Patients may be intubated on an emergency basis in the CCL. Patients with coronary dissection or severe ischemia may require CPR during transport to the operating room.[521] Although the anesthesiologist, cardiologist, or both may lead these resuscitative efforts, all members of the catheterization team—physicians, nurses, and technologists—should complete a course in basic CPR; additionally, certification in advanced cardiac life support, with annual recertification, is strongly urged.[522]

If the patient is not already intubated, the choice of induction agents should be tailored to the patient's hemodynamic condition; one should avoid hypotension and tachycardia while keeping in mind the patient's NPO (nothing by mouth) status. Perioperative monitoring of these patients should include an arterial line and central intravenous access, which should be established as soon as possible. TEE can be of immense importance in both diagnosing the cardiac problem and monitoring the patient intraoperatively.

Other procedures performed in the CCL, invasive vascular laboratory, and electrophysiology laboratory—notably aortic aneurysm stenting and ablation procedures—may also require operating room backup. A dedicated surgical team should be available in the event of a life-threatening complication. Planning for the possibility of conversion to an open procedure, such as in cases of an aneurysm leak or catheter perforation of a major blood vessel or cardiac chamber, is imperative. A hybrid interventional cardiovascular suite is ideal for such events.[523] In institutions without such a hybrid suite, urgent transportation to a general operating room may be necessary.

Optimal care also depends on the ready availability of a stat laboratory. Blood gas analysis, as well as the assessment of electrolytes and hemoglobin or hematocrit, is important in urgent situations. Patients undergoing procedures for coronary revascularization may be receiving platelet inhibitor drugs. Conventional coagulation tests may not be sufficient for diagnosing clinical bleeding in these patients, therefore POC tests that evaluate platelet function and viscoelastic testing to manage perioperative bleeding are useful.[523]

Compared with elective cardiac surgical procedures, emergency cardiac surgery carries higher mortality and morbidity risks, especially if the patient is in cardiogenic shock.[524] Identifying high-risk patients going to the CCL for interventional procedures, as well as communication about these high-risk patients among the interventional cardiologists, cardiac surgeons, and cardiac anesthesiologists, is of prime importance in improving the outcome of these emergency procedures.

Procedures in the Hybrid Operating Room

GENERAL CONSIDERATIONS

Since the 1990s, the scope of activity in the CCL and electrophysiology laboratory has greatly increased and has diverged considerably from the simple diagnosis and evaluation of valvular heart disease, CAD, and CHD.[396,397,522,525] Procedures and interventions in these settings are more complex and often involve acutely ill patients.[397] Cardiac anesthesiologists may find themselves in a relatively isolated environment with bulky equipment, subdued lighting, and limited access to the patient.[521,524] Assistance from surgical colleagues, if required, may not be readily available, nor may the services of anesthesia support personnel, the pharmacy, and the stat laboratory. Finally, for patients with moderate or severe cardiac disease who have undergone heavy sedation or general anesthesia, a suitable recovery area may be in a distant location.

Because fluoroscopy is frequently used during interventional procedures in the CCL and hybrid operating rooms, it can present a significant risk of radiation exposure to both patients and healthcare workers. The potential hazards of ionizing radiation include skin injuries and cellular mutation, which can lead to leukemia, bone cancer, and birth defects. The radiation safety program at the Centers for Disease Control and Prevention (CDC) has developed the concept that radiation doses should be "as low as reasonably achievable" (ALARA). Exposure to radiation can be minimized by three means: distance, time, and shielding.[522] The distance between the person and the source should be maximized because the dose rate varies with the inverse square of that distance. In addition, the person's exposure time should be minimized because the dose rate and time are directly related. Finally, personal shielding and shielding of the radiation source should be maximized.

BOX 54.22 **Maximum Allowable Radiation Limits for Medical Workers**

- Whole body: 5 rem/year (50 mSv/year)
- Skin: 50 rad/year (500 mGy/year)
- Lens of eye: 2 rad/year (20 mGy/year)
- Fetus (for pregnant worker): 0.5 rad (5 mGy) for total pregnancy or 0.05 rad/month (0.5 mGy/month) (estimated by abdominal badge under lead apron)
- Cumulative exposure (lifetime): 1 rem × age (10 mSv × age)

Modified from Bashore TM, Balter S, Barac A, et al. 2012 American College of Cardiology Foundation/Society for Cardiovascular Angiography and Interventions expert consensus document on cardiac catheterization laboratory standards update: a report of the American College of Cardiology Foundation Task Force on Expert Consensus documents. *J Am Coll Cardiol.* 2012;59:2221–2305.

The rad is a unit of absorbed dose, which is the energy imparted to matter by ionizing radiation per unit mass of irradiated material at the point of interest.[522] The rem is a unit of effective dose, which is the estimated total body dose. Healthcare personnel in a radiation environment must wear a dosimeter badge to track cumulative radiation exposure. The dosimeter should be worn on areas at highest risk for frequent exposure, such as the thyroid collar, and outside any shielding garments. Corrective action is recommended if an individual (patient or provider) receives more than 5 rem/year to the whole body (Box 54.22).[522] In the case of pregnant women, the total radiation exposure to the fetus throughout gestation should be no more than 0.05 rad/month or 0.5 rad total.

Identifying patients at risk for a reaction to iodinated contrast material is another consideration unique to procedures performed in the CCL or hybrid suite. A previous anaphylactoid reaction and a history of atopic conditions such as asthma are the most significant risk factors for acute hypersensitivity reactions.[522] Premedication regimens with histamine (H_2) blockers and steroids are recommended for the highest-risk atopic patients, particularly those with a known prior reaction. Current options include giving 50 mg oral prednisone 13 hours, 7 hours, and 1 hour before the procedure or 200 mg intravenous hydrocortisone, with or without H_2 blockers, 2 hours before the cardiac catheterization.[522]

In patients with renal insufficiency, radiocontrast media–induced nephropathy is a concern, and diabetic patients are at particularly high risk for acute renal failure after exposure to contrast agents.[521,522] These effects can be minimized through careful contrast administration and limitation of the total dose. Preprocedural and postprocedural hydration with normal saline solution, sodium bicarbonate, or both is recommended.[522] However, in patients with severe HF or near–end-stage renal disease, one must be careful to avoid volume overload.[521,522] Elevated serum creatinine levels are common after the administration of radiocontrast media, and these levels should be monitored for 72 or more hours in patients at risk. Two definitions (an incremental increase >0.5 mg/dL or a rise >25% in serum creatinine level) are now accepted as indicators of contrast-induced nephropathy. Fortunately, renal dysfunction is usually transient and rarely progresses to acute renal failure.

HYBRID OPERATING ROOM

To address some of the issues regarding the technologic and procedural demands regarding surgical and imaging equipment for selected endovascular and transcatheter procedures, hybrid operating rooms have been built in many institutions. These rooms have complete dual capabilities for procedures that require fluoroscopy, open surgery, or both. Ideally, such rooms are within or adjacent to the regular surgical suite. The physical location of such hybrid rooms may represent an advance in care in that key personnel are more readily available to handle unanticipated complications and emergencies.

The types of procedures that are performed in the CCL or the hybrid operating room vary according to institutional preferences but may include (1) electrophysiology procedures, (2) percutaneous management of valvular lesions, (3) the use of occlusion or umbrella devices to close an ASD or VSD or a PDA, (4) percutaneous VADs, and (5) stenting of abdominal or thoracic aortic aneurysms.[400-402]

Although requirements vary depending on the nature of the procedure, sedation or anesthesia improve the efficacy and safety of many procedures.[525] Providing stable hemodynamics for organ perfusion and preservation during anesthesia is an important goal. Some procedures can be performed with the aid of monitored anesthesia care or regional blocks, provided a certain patient comfort level can be achieved. However, during difficult and lengthy procedures, patients may have trouble lying still. In many cases, a general anesthetic regimen may be the best option. If indicated, general anesthesia with endotracheal intubation provides a controlled situation: the patient's comfort is maximized, and the airway is secured.[521] Use of a laryngeal mask or a standard mask airway is also possible, but the constant diaphragmatic movements that occur during spontaneous ventilation may interfere with fluoroscopic visualization of cardiac and vascular structures. In the absence of significant complications or comorbid conditions, the patient may be allowed to emerge from anesthesia before being transferred to the CCL recovery area and, eventually, to a hospital floor. In more complex cases, the patient may be transferred to an ICU.

Percutaneous mitral valve repairs (e.g., correction of MR and commissurotomy for MS) share the same advantages as TAVI with respect to avoiding sternotomy, implementing CPB, and cross-clamping the aorta.[399] These procedures are similarly performed with the patient under general anesthesia, with fluoroscopic and TEE guidance.[402]

Percutaneous closure procedures are used to close ASDs and, less commonly, VSDs, as well as PDAs and fenestrations.[402,525] Echocardiography is used to help guide device placement and confirm a successful result. If TEE is used, general anesthesia is necessary. If ICE is used, the procedure can potentially be performed with sedation only.[402] Large-bore peripheral or femoral venous access is needed, and a radial arterial line is often placed.

Percutaneous VADs (TandemHeart, and Impella Recover LP 2.5 and 5.0) are placed in patients undergoing high-risk coronary interventions or ablation procedures or who are in cardiogenic shock.[402] These devices can produce CO that completely replaces LV function with nonpulsatile blood flow. Hence, pulse oximetry and noninvasive blood pressure measurement may not work properly since they rely on the presence of a pulse for their mechanism of measurement. Either sedation or general anesthesia can be used, depending on the patient's hemodynamic status and ability to cooperate. Invasive monitoring of the arterial blood pressure is easily available because arterial cannulation is used during the procedure.[402] Large-bore intravenous access is desirable because a large amount of blood loss is possible. Surgical backup is necessary during these procedures. The institution of ECMO for full cardiorespiratory support is often performed in a catheterization laboratory or a hybrid operating room.

Acknowledgment

This chapter consolidates the 8th edition chapter of the same title and Chapter 104 Nitric Oxide and Other Inhaled Pulmonary Vasodilators. The returning authors Muhammad F. Sarwar Bruce E. Searles, Linda Shore-Lesserson, and Marc E. Stone as well as the editors and publisher would like to thank the following authors: Nancy A. Nussmeier, Isobel Russell, Fumito Ichinose, and Warren M. Zapol for their contributions to the prior edition of this work. It has served as the foundation for the current chapter.

Anesthesia for Correction of Cardiac Arrhythmias

SAMUEL A. IREFIN

KEY POINTS

- Cardiac arrhythmias are caused by disorders of impulse formation, disorders of impulse conduction, or both. Cardiac arrhythmias may be life-threatening because of a reduction in cardiac output and/or myocardial blood flow or precipitation of a more serious arrhythmia.
- Radiofrequency ablation is the therapy of choice for many types of cardiac arrhythmias.
- Electrophysiologic studies are used to map out normal and abnormal intracardiac structures. In this process, the mechanism of arrhythmia is delineated and ablation can be performed at the same time.
- Pacing technologies have been developed to treat heart failure resulting in increases in pulse pressure, left ventricular stroke volume, cardiac index, and wedge pressure.
- Implantable pacemakers are placed for treatment of symptomatic bradycardia with the ability to respond to changing hemodynamic demands.
- The development of implantable cardioverter-defibrillators (ICDs) to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle has revolutionized therapy for cardiac arrhythmias.
- The main purpose of ICD placement is to prevent sudden cardiac death resulting from hemodynamically unstable ventricular arrhythmias.
- An ICD can be placed for cardiac resynchronization. Cardiac resynchronization therapy improves heart failure symptoms, quality of life, exercise capacity, and electrocardiographic variables.
- Anesthetic management of patients for correction of cardiac arrhythmias depends on associated comorbid illness and the procedure that is planned.

In the United States, cardiac arrhythmias are responsible for about 1 million hospitalizations and nearly 50,000 deaths.[1] Pharmacotherapy with potentially toxic medications was used to treat cardiac arrhythmias in the past but electrophysiology has transformed the care of patients with arrhythmias from diagnostic studies to direct therapeutic interventions, as demonstrated in clinical trials. Cardiac arrhythmias are caused by disorders of impulse formation, disorders of impulse conduction, or both. Disorders of impulse formation include enhancement or depression of automaticity, parasystolic activity, and triggered activity. Disorders of conduction include decremental conduction, reentry, entry block, exit block, concealed conduction, and supernormal conduction.[2]

At the present time, radiofrequency catheter ablation has replaced antiarrhythmic drug therapy as the treatment of choice for many types of cardiac arrhythmias. Before the 1980s, cardiac electrophysiology was primarily used to confirm mechanisms of arrhythmias, with management mainly by pharmacologic means. As a result of shortcomings in antiarrhythmic drug therapy (including the results of randomized trials), radiofrequency ablation and implantable cardioverter-defibrillators (ICDs) were developed.[3,4]

Historical Perspectives

The treatment of cardiac arrhythmias with device-based therapy may have begun in 1899, when Prevost and Batteli[5] noted almost as an afterthought that direct electric shock could terminate ventricular fibrillation in dogs. Hooker and colleagues[6] showed three decades later that the passage of electric current across the heart can initiate and terminate ventricular fibrillation. In 1947, Beck[7] saved the first human life by the successful use of cardiac defibrillation in a 14-year-old boy who developed ventricular fibrillation during a thoracic procedure and went on to achieve full recovery. These early achievements provided the foundation for the landmark work of Mirowski and Mower[8] which ultimately led to the development of ICDs in humans in 1980. During the past three decades, an increase has occurred in the numbers of patients with pacemakers and ICDs for the correction of cardiac arrhythmias.

Scope of Cardiac Arrhythmias

Cardiac arrhythmias are common. Some cardiac arrhythmias are life-threatening, and others are merely a nuisance.

Cardiac arrhythmias are caused by abnormalities in impulse formation or conduction that lead to slow or fast, regular or irregular heart rhythms. At the present time, it is not difficult to treat slow rhythms because available pacemakers are able to adapt slow function to the needs of the body.[9] The situation is different, however, for patients with rapid rhythms. Rapid rhythms may originate anywhere in the heart and result from various mechanisms. These mechanisms may be focal, meaning that the abnormal impulse formation is confined to a small area, or they may be the result of an impulse running in a circuit composed of several interconnected cardiac cells. Such a circuit may be small or large, as in atrial flutter and in arrhythmias in which the normal atrioventricular conduction system and an extra connection between the atrium and the ventricle are incorporated into the circuit of the arrhythmia.[10]

Pharmacologic interventions originally were used to terminate and prevent rapid rhythms. However, antiarrhythmic drugs may have serious side effects and sometimes may even be responsible for the occurrence of life-threatening arrhythmias and sudden death.[11] As a result of these effects, techniques were developed for localizing the site of origin or pathway of an arrhythmia and then isolating or destroying the tissue that is responsible. By employing an intracardiac catheter, the site of origin or pathway of an arrhythmia can be identified and the rhythm disturbance corrected by applying radiofrequency, laser, ultrasound, microwave energy, or freezing temperatures to the tissue causing the arrhythmia.

Heart failure is a major problem in older patients. Although pharmacologic treatment of heart failure has improved, outcome generally remains poor. New pacing technologies may be used to treat selected patients with heart failure. For many years, permanent pacing has been used to treat symptomatic bradycardia, and pacing may alleviate heart failure when associated with heart block. Several studies have examined the use of conventional dual-chamber atrioventricular–right ventricular pacing for treatment of heart failure in the absence of symptomatic bradycardia or heart block.[4,12] Biventricular pacing aims to restore synchronous cardiac contraction. When ventricular dyssynchrony is reduced, the heart is able to contract more efficiently and increase left ventricular ejection fraction and cardiac output, while working less and consuming less oxygen.[13] In addition, reestablishment of left ventricular synchrony can increase left ventricular filling times, decrease pulmonary capillary wedge pressure, and reduce mitral regurgitation.

Normal Cardiac Rhythm

In the normal heart, the dominant impulse arises in the sinus node with a rate of 60 to 100 beats/min (Fig. 55.1). During sleep, the rate may decrease to 30 to 50 beats/min.[14] Episodes of sinus pauses up to 3 seconds, sinoatrial block, junctional rhythms, and first-degree and second-degree atrioventricular nodal block that occur quite often (especially in trained athletes) are considered to be normal variants.[9]

The impulses generated from the sinoatrial node propagate along three intraatrial conduction pathways: the anterior, middle, and posterior internodal tracts. These tracts are not discrete pathways, but groups of cells that conduct slightly faster than the atrial myocardium.[15] The internodal tracts give rise to interatrial fibers. The electric impulse, whether propagated in the atrial myocardium or along the internodal tracts, converges on the atrioventricular junction. The atrioventricular node located in the atrioventricular junction ultimately receives the impulses generated from the sinoatrial node. The impulses are delayed in the atrioventricular node before they are finally distributed to the ventricular myocardium via the His-Purkinje system.

Normally, the heart rate increases with exercise to at least 85% of the age-predicted maximum of 220 minus age in years; failure to do so is termed chronotropic incompetence. Sinus arrhythmia is defined as sinus rhythm with P-to-P variations of more than 10% (Fig. 55.2). Sinus arrhythmia is due to cyclic variations in vagal tone commonly related to respiration (the rate is faster with inspiration and slower with expiration).[16] Sinus arrhythmia disappears with exercise, breath-holding, and atropine, and is more likely to be seen in individuals who do not have heart disease.[17]

Cardiac Arrhythmias

Cardiac arrhythmia is caused by a disorder of impulse generation, impulse conduction, or a combination of both. Cardiac arrhythmia may be life-threatening because of

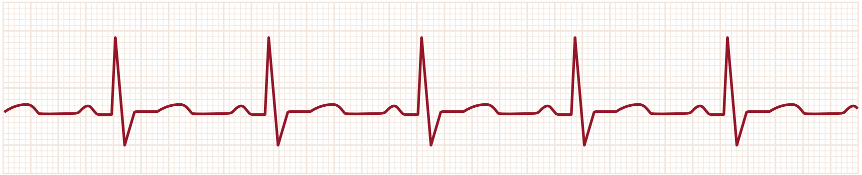

Fig. 55.1 Normal sinus rhythm. (Courtesy M. Kanj, MD, Cleveland Clinic, Cleveland, OH.)

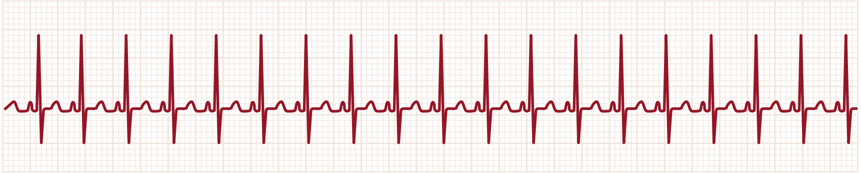

Fig. 55.2 Sinus arrhythmia. (Courtesy M. Kanj, MD, Cleveland Clinic, Cleveland, OH.)

a reduction in cardiac output, reduction in myocardial blood flow, or precipitation of a more serious arrhythmia.[18] Arrhythmias may be described based on (1) rate (bradycardia or tachycardia), (2) rhythm (regular or irregular), (3) origin of impulse (supraventricular, ventricular, or artificial pacemaker), (4) impulse conduction (atrioventricular, ventriculoatrial, or block), (5) ventricular rate, or (6) special phenomena (e.g., preexcitation).

Reentry is a common electrophysiologic mechanism that predisposes to most ventricular arrhythmias and to most supraventricular tachyarrhythmias. The most common mechanism of reentry is based on the model originally proposed by Erlanger and Schmitt and later modified by Wit.[2] This model postulates the presence of a ring or loop of cardiac tissue that is functionally separate from neighboring tissue and the presence of transient or permanent unidirectional block in a portion of the loop. Unidirectional block may be anatomic in origin (e.g., bundle branches, fibrosis, dual pathways, atrioventricular node plus accessory pathway) or functional (e.g., ischemia, drug effect).

Atrial flutter is a macro-reentrant arrhythmia identified by flutter waves, often best seen in the inferior leads at 250 to 350 beats/min (Fig. 55.3). Patients often present with a 2:1 atrioventricular conduction with a ventricular rate of 150 beats/min, although the atrioventricular conduction ratio can change abruptly. Atrial fibrillation is a narrow-complex tachyarrhythmia and is the most common in the general population (Fig. 55.4). It is associated with significant morbidity. The prevalence of atrial fibrillation in the general population increases exponentially with age, from 0.9% in individuals 40 years of age to 5.9% in individuals older than age 65 years. The most important risk factors for development of atrial fibrillation in the general population are structural heart disease, valvular heart disease, and left ventricular hypertrophy.[19] Atrial fibrillation is a significant contributor to the development of angina and stroke, with an estimated stroke risk in untreated individuals of 3% to 5%.[20]

Ventricular tachyarrhythmia is defined as three or more consecutive ectopic beats at a rate more rapid than 100 beats/min (Fig. 55.5).[21] Ventricular tachyarrhythmia is traditionally classified as nonsustained or sustained. Sustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia lasting more than 30 seconds. Nonsustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia that terminates spontaneously within 30 seconds. Sustained ventricular tachyarrhythmia also is traditionally classified as monomorphic (one site of origin) or polymorphic (two or more sites of origin).[22] Monomorphic ventricular tachyarrhythmia usually results from reentry, and the site of reentry depends in part on the type of heart disease. In patients with coronary artery disease, the reentry circuit is usually located in ventricular myocardium, whereas in dilated cardiomyopathy with left bundle branch block, bundle branch reentry is common.[23] Monomorphic ventricular tachyarrhythmia may occur in individuals with an otherwise normal heart, whereas polymorphic ventricular tachyarrhythmia may occur in acquired states that produce a marked prolongation of the Q-T interval. Nonsustained ventricular tachyarrhythmia is frequently asymptomatic, but may produce palpitations, weakness, and presyncope.[22]

Torsade de pointes is a French term translated as "twisting of the points." It is a syndrome composed of polymorphic ventricular tachyarrhythmia (Fig. 55.6). It may be due to various medications or electrolyte imbalances. Torsade de pointes is usually paroxysmal, but is frequently symptomatic and often produces loss of consciousness. It

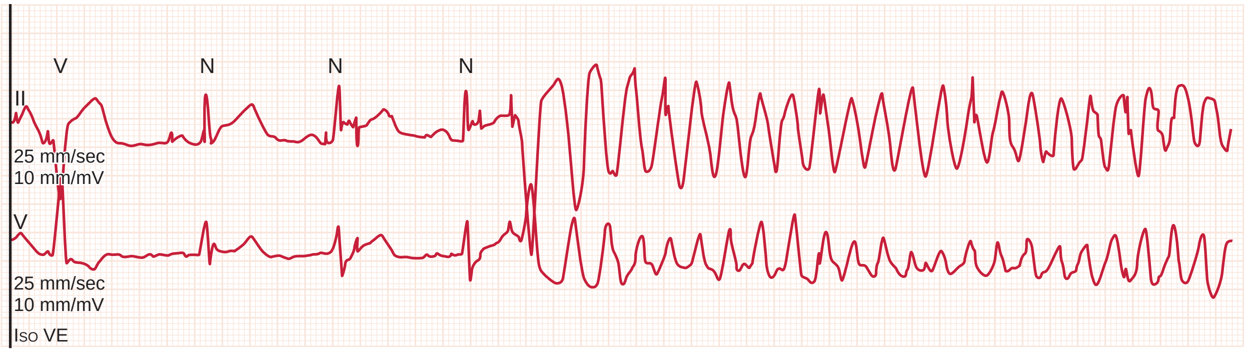

Fig. 55.6 Torsade de pointes. (Courtesy M. Kanj, MD, Cleveland Clinic, Cleveland, OH.)

occasionally degenerates to ventricular fibrillation. Ventricular fibrillation accounts for 80% to 85% of sudden cardiac deaths.[22]

Ventricular fibrillation is usually preceded by ventricular tachyarrhythmia, but also may occur as a primary arrhythmia (Fig. 55.7). More recent studies suggest that ventricular fibrillation results from multiple wavelengths that disperse randomly, using the leading circle form of reentry.[22] The most common cause of ventricular fibrillation is acute myocardial infarction. It also is observed in patients with chronic ischemic heart disease, hypoxia resulting from any cause, acidosis, hypokalemia, and massive hemorrhage.

INDICATIONS FOR CORRECTION OF CARDIAC ARRHYTHMIAS

Intracardiac electrophysiologic studies can give valuable information about normal and abnormal electrophysiology of intracardiac structures (see also Chapters 36, 38, and 86). These studies are used to confirm the mechanism of an arrhythmia, to delineate its anatomic substrate, and to ablate it. The electric stability of the ventricles also can be assessed, as can the effects of an antiarrhythmic regimen.

In addition, pacing technologies have been developed to treat heart failure with promising results, leading to

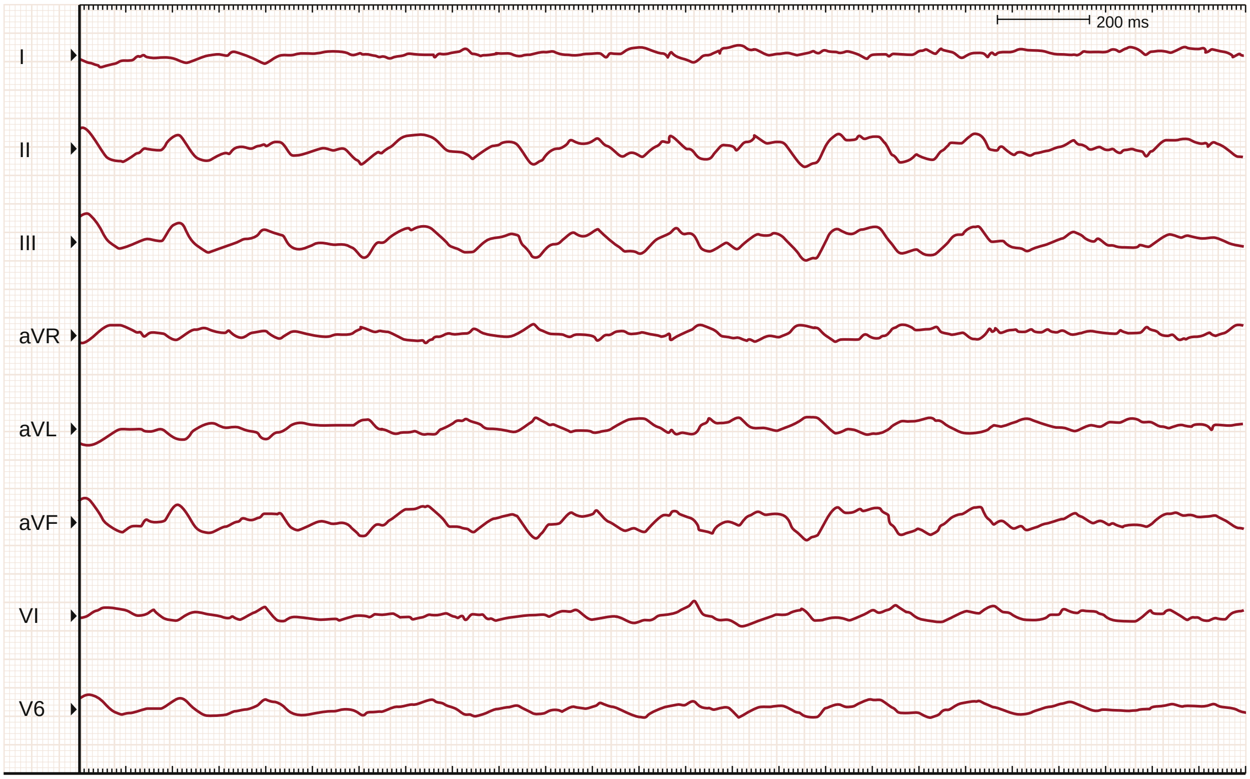

Fig. 55.7 Ventricular fibrillation. (Courtesy M. Kanj, MD, Cleveland Clinic, Cleveland, OH.)

improvement in morbidity and mortality in patients with heart failure.

Hemodynamic responses to biventricular pacing include an increase in the rate of elevation of left ventricular pressure and increases in pulse pressure, left ventricular stroke work, cardiac index, and wedge pressure.[23] Cardiac resynchronization therapy improves ventricular function without increasing myocardial energy consumption, in contrast to the effect of inotropic agents, such as dobutamine.[13] In addition, cardiac resynchronization therapy may reverse left ventricular remodeling over time.[24]

Permanent Pacing

Indications for pacemaker therapy have increased in recent years and now include the treatment of bradyarrhythmias and heart failure according to the American College of Cardiology and American Heart Association guidelines.[25] These guidelines discuss indications for pacing in patients with sinus node dysfunction, acquired atrioventricular block, chronic bifascicular and trifascicular block, hypersensitive carotid sinus, and neurally mediated syndromes. The guidelines direct the treating physician in selecting patients who would benefit from device therapy.

A Swedish team led by Sennings and Elmqvist implanted the first pacemaker in 1958.[26] A thoracotomy was required, and pacing was done through electrodes sutured to the epicardium. In these early systems, significant problems with changes in pacing threshold, lead infection, and lead breakage were common. Transvenous lead implantation subsequently developed by Furman and colleagues[27] would resolve many of these issues. In 1958, Furman successfully paced an elderly patient with a catheter electrode inserted transvenously. Other investigators took on the challenge of solving various technical problems, such as device miniaturization; longer-life batteries; and stable, reliable lead material.[28] As the indication for implantation expanded from atrioventricular conduction disturbances to management of sinus node dysfunction, the need for implantable pacemakers grew in proportion.[28] Technology evolved rapidly with the development of lithium-iodide batteries that had greater longevity. Electronic advances then led to major miniaturization using integrated circuits as opposed to discrete components. Lead materials used in today's pacemaker rely on silicone and polyurethane, which are more biocompatible and reliable than earlier materials. With these technical refinements, present-day pacemakers are small and can pace reliably for 8 to 10 years before generator replacement is needed. The primary functional challenge for contemporary pacemakers is to maintain the heart rate based on circulatory needs, pacing in a manner that mimics the natural physiology of excitation and conduction. In a healthy heart, the sinus node is modulated by the autonomic nervous system, and its rate is determined by a multiplicity of factors, such as physical activity, emotion, and blood pressure. Not only the rate, but also the activation sequence and atrioventricular conduction time vary with demand; these requirements also must be considered. Rate is controlled by pacemaker discharge, and the excitation and conduction sequence depends on the placement of pacing electrodes. Approximately 120,000 pacemakers are implanted each year in the United States. Indication for implantation for most of these cases is sick sinus syndrome.

Other indications include atrioventricular block, carotid sinus hypersensitivity, malignant vasodepressor syndrome, and hypertrophic cardiomyopathy.[29] The primary purpose of implantable pacemakers is to treat symptomatic bradycardia. With the extraordinary developments that have occurred in pacemaker therapy for the traditional indication—bradycardia—new uses are now beginning to be explored. Pacemakers have progressed from large, fixed-rate, single-chamber devices to multiprogrammable, multichamber devices with the ability to respond to changing hemodynamic demands. As technology advances, other possible uses are likely to be conceived.

Resynchronization Therapy

Cardiac resynchronization is a pacing therapy aimed at improving coordination of atria and both ventricles. This therapy has been demonstrated to be effective for patients with heart failure who have conduction delay and left ventricular systolic dysfunction.[30] In addition, this therapy can reduce hospital readmission rates and improve quality of life in patients with heart failure.[31]

Cardiac resynchronization therapy improves heart failure symptoms, quality of life, exercise capacity, hospitalization, and echocardiographic variables.[32] It is indicated in patients with drug-refractory, symptomatic New York Heart Association functional class III and IV heart failure of either ischemic or nonischemic origin.[31] In addition, these patients are protected from associated risk for sudden cardiac death when combined with an ICD system.[30]

The development of an automatic internal defibrillator, or ICD, began in the 1960s. External cardiac defibrillation was increasingly being used in coronary care units for the treatment of ventricular fibrillation and sudden cardiac death. Although the idea of automatic external defibrillation had been discussed initially by Zycoto, Mirowski, and colleagues[33] were the first to champion and begin practical development of an automatic internal device. In 1969, Mirowski and Mower developed the prototype of today's automatic internal defibrillator.[34]

The primary goal of all defibrillators is to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle. As with implantable pacemakers, defibrillating devices need to be small and reliable and have adequate longevity. ICDs have evolved not only to perform this function but also to take on additional tasks, such as antitachycardia pacing of the ventricle, dual-chamber pacing, and termination of atrial tachyarrhythmias.

A key difference between pacing and defibrillation of the heart is that for pacing only a very small mass of myocardium needs to be stimulated, whereas for defibrillation, most, if not all, of the myocardium must be stimulated. Because the myocardium is easily excitable throughout diastole, a small wave of depolarization during pacing can readily propagate throughout the whole heart. In contrast, during ventricular fibrillation, multiple reentrant wavefronts usually occur that are continuously changing in location and size and must be quelled. To defibrillate successfully, most of these wavefronts must be interrupted simultaneously; to achieve this, it is necessary to capture most of the tissue that is in a state of relative refractoriness.[35] One unique property of defibrillation success is that it is probabilistic.[36] The same energy that can defibrillate the heart on one occasion may be unsuccessful at another time.

The main purpose of ICD placement is to prevent death from hemodynamically unstable ventricular tachyarrhythmias. Although advances in technology have made these devices much more flexible in terms of arrhythmia detection and electric therapy potions, their main purpose is to reduce sudden cardiac death, which claims approximately 300,000 lives in the United States annually. Secondary prevention of sudden cardiac death in patients who have survived cardiac arrest is another major indication for ICD placement. In such patients and especially in patients of this group for whom no reversible or curable cause can be found, ICD implantation has been repeatedly documented to provide a major mortality benefit.[37] Interest in managing atrial tachyarrhythmias also has grown significantly in recent years. It is now recognized that approximately 30% of patients with ventricular tachyarrhythmia also have atrial tachyarrhythmias.[38] Such atrially initiated tachyarrhythmias can worsen patient symptoms, can result in inappropriate ventricular shocks, and may be responsible for initiating ventricular tachyarrhythmias that can exacerbate other pathologic processes, such as heart failure. New strategies for treatment and prevention of atrial tachyarrhythmias are incorporated into devices that are capable of defibrillation and anti-tachycardia pacing in the atrium and ventricle, in addition to combined dual-chamber pacing.[39]

The relative ease of ICD implantation and longevity of current defibrillators have made them a valuable tool in primary prevention. Patients no longer must survive cardiac arrest to justify the risk in ICD implantation.

PREOPERATIVE EVALUATION

Most patients who require pacemaker or ICD placement have significant cardiovascular disease. In addition, correction of cardiac arrhythmia may require radiofrequency catheter ablation. Radiofrequency catheter ablation has proved highly effective in the treatment of atrioventricular nodal reentrant and accessory pathway tachycardias. Indications for pacemaker and ICD placement continue to evolve as the utility of these devices continues to increase. Although most pacemaker placement is done with local anesthetic infiltration, ICD placement may require monitored anesthesia care or in some cases general anesthesia. The modern ICD unit is capable of delivering the full spectrum of therapy for ventricular tachyarrhythmias and for bradycardia therapy with dual-chamber pacing or sensing, rate modulation, and mode-switching features.

As mentioned earlier, ICD placement has two common indications. One is continued ventricular tachyarrhythmias despite adequate drug therapy, and the other is history of sudden cardiac arrest that is not associated with myocardial infarction. Preoperative evaluation processes necessary for placement of an ICD should be complete by the time the decision is made to place the device. These patients need a thorough preoperative evaluation. This evaluation includes electrophysiologic testing to determine the inducibility of ventricular tachycardia and electrophysiologically guided drug therapy. Preoperative pulmonary function tests may be necessary in patients on amiodarone to evaluate possible toxicity of this drug, which can result in chronic obstructive pulmonary disease or interstitial lung disease. In some instances, the underlying pathophysiology of malignant ventricular arrhythmias is related to ischemic or idiopathic cardiomyopathy.[40] These patients often present with poor left ventricular function and more frequent incidence of congestive heart failure. Patients with a history of congestive heart failure should be in optimal condition before surgery.

Generally, all patients who present for correction of cardiac arrhythmia require preoperative evaluations including electrocardiogram (ECG), chest radiograph, hemoglobin value, and electrolyte levels. Patients should receive nothing by mouth (NPO) for at least 8 hours before the procedure. In addition, patients who require device and lead extractions because of malfunction or infection may require blood product transfusions during the procedure. Consequently, type and crossmatch of blood products is frequently necessary for these procedures.

ANESTHETIC CONSIDERATIONS

Pacemakers

Permanent implantable pacemakers have been the standard modality of treatment for patients with all types of bradyarrhythmias. A significant number of these patients present with sick sinus syndrome and are older. Consequently, devices are placed under general anesthesia in these patients. As a result of more recent advances in pacemaker technology, these devices now can be placed as a therapeutic modality to alter hemodynamic states. Surgeons used to be primarily responsible for device insertion. Now the task falls under the services of cardiologists. Device placement is commonly performed in the cardiac catheterization suite under local anesthesia on an outpatient basis. Patients at high risk who have complicated disease now present for pacemaker insertion, however, in addition to those with indications more recently identified by the American College of Cardiology and American Heart Association for these devices. In light of these increased indications, the expertise of anesthesiologists is needed for monitoring and perioperative care of these patients.

Monitored Anesthesia Care

Currently, most pacemaker insertions are performed by cardiologists. Most of these cases are performed under local anesthesia with sedation. Depending on the level of training, administration of sedatives and analgesics can be provided by nurses.

In instances that require deeper sedation for a patient's comfort or for critically ill patients with hemodynamic instability, monitored anesthesia care by an anesthesiologist may be required. Adequate monitoring and resuscitation equipment are required in such situations. The goal of monitored anesthesia care is to provide analgesia, sedation, and anxiolysis, while ensuring rapid recovery with minimal or no side effects. Any sedative-hypnotic medication may be used during monitored anesthesia care with a wide variety of delivery systems.[41] Subanesthetic concentrations of inhaled agents also have been used to supplement local anesthetics. Newer drugs, such as centrally mediated α_2-agonists, have been shown to produce anxiolysis, sedation, and reduced requirements for supplemental analgesic medications during monitored anesthesia care.

General Anesthesia

Patients requiring pacemaker placement rarely require general anesthesia for placement. If general anesthesia is required, it should be directed toward underlying cardiac pathophysiology, indications, complications, and hemodynamic goals. Immediate access to life-support equipment, such as a cardiac defibrillator and a transcutaneous pacemaker, is necessary if the device is being placed under general anesthesia.

Implantable Cardioverter-Defibrillator

Since the 1980s, indications for use and implantation of ICDs have steadily increased. Over the past two decades, ICDs have undergone a significant evolution. In the 1970s and 1980s, ICD placement usually required thoracotomy for placement of epicardial patches.

PREOPERATIVE EVALUATION

As mentioned earlier, common indications for ICD implantation include continued ventricular tachyarrhythmias unresponsive to adequate pharmacotherapy and history of sudden cardiac arrest unassociated with myocardial infarction. Newer indications include patients with various forms of the congenital long QT syndrome.[42] Patients with long QT syndrome who have survived an episode of cardiac arrest or documented polymorphic ventricular tachyarrhythmia, especially if on pharmacotherapy at the time, are increasingly being evaluated as ICD candidates. In addition, patients with hypertrophic cardiomyopathies and without a history of sudden death are usually evaluated for ICD placement.[43] In these patients, sustained ventricular arrhythmias, nonexertional syncope, or a strong family history of sudden death with early age of presentation strongly indicates ICD implantation.

In all instances, the evaluation that is necessary for ICD implantation is completed by the time the decision is made to place the device. Electrophysiologic studies may have been done to determine the forms of arrhythmias present. When the pathophysiology of ventricular arrhythmias is related to idiopathic or ischemic cardiomyopathy,[44] these patients may present with poor left ventricular function and a high incidence of congestive heart failure. Consequently, they should be optimized as much as possible preoperatively.

ANESTHETIC CONSIDERATIONS

In the 1980s, ICD implantation was done with epicardial leads via thoracotomy under general anesthesia with one-lung ventilation. The technologic development of implantable ICDs with transvenous lead systems has simplified their implantation. Consequently, it was reasoned that ICDs can be placed under deep sedation with little or no intervention by the anesthesiologist analogous to what is needed for pacemaker placement.[45] Placement of an ICD under general anesthesia may be safer and more comfortable for the patient, however. Patients who present for ICD placement are often critically ill with cardiopulmonary comorbidity. These patients often present with ejection fractions of less than 30% and require vasopressors to support hemodynamics during the procedure. In addition, some form of general anesthesia is necessary for intraoperative testing of defibrillating thresholds.

Monitored Anesthesia Care

Small, new-generation devices and transvenous lead systems lend themselves to the use of local anesthesia and intravenous sedation for ICD implantation. Midazolam and fentanyl are usually the drugs of choice when an ICD is placed under monitored anesthesia care. Monitoring includes pulse oximetry, five-lead ECG, and noninvasive blood pressure. Depth of anesthesia is monitored clinically. One of the major aspects of ICD placement is testing the device. Testing the device may require deep sedation or general anesthesia because the shocks associated with this procedure can be very painful. The presence of an anesthesiology team may be necessary for ICD placement under monitored anesthesia care.

General Anesthesia

Most patients who present for ICD placement typically have comorbidities such as ventricular tachycardia, congestive heart failure with ejection fraction less than 30%, coronary artery disease, pulmonary hypertension, chronic renal insufficiency, or valvular heart disease. These patients may be unable to lie flat for the prolonged period necessary for placement of the ICD. In addition, they may require close hemodynamic monitoring during testing of the device. General anesthesia should be considered in these patients. When general anesthesia is chosen, in addition to standard monitoring, an arterial line may be added. External cardioverter-defibrillator pads are required for all ICD placements. These are employed in cases in which an implanted defibrillator fails. General anesthesia also may be requested for anxious and extremely nervous patients. Because pacemakers and ICDs are placed percutaneously, anesthesiologists must be vigilant for possible complications, such as myocardial infarction, stroke, possible cardiac injury (perforation or tamponade), and pneumothorax from subclavian vascular access.

EXTRACTION OF DEVICES

As a result of continued growth and expanding indications for pacemakers and ICD placement, leads may require extraction because of mechanical dysfunction, the need to upgrade to more complex devices, or local or systemic infection. Lead extractions are probably one of the most challenging procedures that a cardiac electrophysiologist faces today.

Indications for lead extractions can be divided into two categories—patient-related and lead-related. Patient-related indications include infection, ineffective therapy (high defibrillation threshold), perforation, migration, embolization, induction of arrhythmias, venous thrombosis, unrelenting pain, device interactions, and device upgrades.[46] Lead-related indications include lead recalls, lead failure, and lead interactions.[47] Lead extraction is performed via powered sheaths through which energy is delivered to the tip in the form of excimer laser light or electrocautery. These systems burn through scar tissue adherent to the wall of the lead throughout its course. The potential for life-threatening complications, such as lead fracture, venous or myocardial rupture, and tamponade, makes general anesthesia with invasive monitors a prudent choice for lead extractions. There is also a small chance of needing emergent cardiac surgery with lead extraction and therefore the team must be vigilant for signs of cardiovascular decompensation.

POSTOPERATIVE CARE

Postoperative care of patients with pacemaker or ICD implantation depends on various factors surrounding the implantation of the device. As mentioned earlier, most of these patients are quite ill with significant comorbidities. It is not unusual for patients to have congestive heart failure with an ejection fraction less than 30% as a result of poor left ventricular function. Consequently, it is imperative to have these patients monitored in the postanesthesia care unit, especially if the device is placed or extracted under general anesthesia. The spectrum of recovery sites after these procedures may vary from postprocedure units to a coronary intensive care unit. Most of these procedures are done on an outpatient basis, and anesthesia is tailored to ensure rapid recovery after implantation.

Correction of Cardiac Arrhythmias With Ablation Therapy

Catheter ablation is a safe and curative option for most cardiac arrhythmias, with 85% to 98% cure rates among the arrhythmias treated most frequently.[48] The rate of major complications is less than 3%.[48] Cardiac ablation therapy involves the delivery of energy through a catheter that is usually placed in the endocardial position in the heart, destroying myocardial tissue that is responsible for the tachyarrhythmia (Fig. 55.8). Multiple electrodes are inserted to locate the arrhythmia and ablate it. Usually the diagnostic portions of the ablation study are done during the same procedure.[49] The efficacy of catheter ablation depends on accurate identification of the site of origin of the arrhythmia. When the site is identified, the electrode catheter is positioned in direct contact with the site of the arrhythmia, and radiofrequency energy is delivered through the catheter to destroy it.

The current generated by radiofrequency is alternating current and is delivered at cycle lengths of 300 to 750 kHz when used for catheter ablation.[50] It causes resistive heating of the tissue in contact with the electrode. The degree of tissue heating is inversely proportional to the radius to the fourth power.[51] Consequently, the lesions created by radiofrequency energy are small. Although electric injury may be a contributing factor, the primary mechanism of tissue destruction by radiofrequency current is thermal injury. Acute lesions created by a radiofrequency current consist of a central zone of coagulation necrosis surrounded by a zone of hemorrhage and inflammation.[52] Cardiac arrhythmias

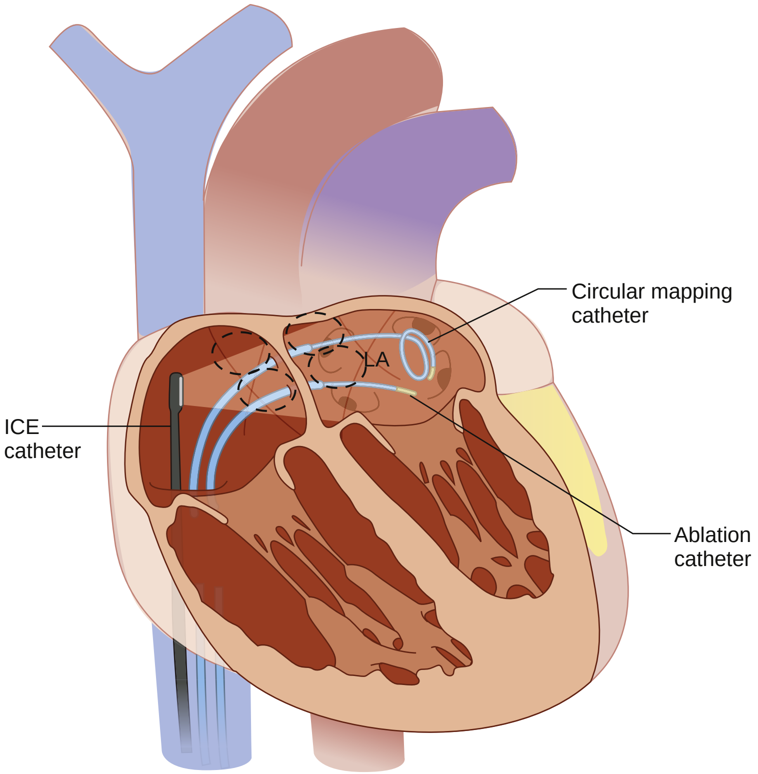

Fig. 55.8 Catheter placement during ablation procedures. Mapping and ablation catheters were placed under the guidance of intracardiac echocardiography. *ICE,* Intracardiac echocardiography *LA,* Left atrium. (Courtesy O. Wazni, MD, Cleveland Clinic, Cleveland, OH.)

that can be treated with radiofrequency ablation include paroxysmal supraventricular tachycardia, Wolff-Parkinson-White syndrome, atrial flutter, atrial fibrillation, and idiopathic ventricular tachycardia. Most cardiac arrhythmias treated with radiofrequency ablation are not life-threatening but have a significant impact on a patient's quality of life.[53] Advantages of radiofrequency ablation of cardiac arrhythmias include relief of symptoms, improvement in functional capacity and quality of life, and elimination of the need for lifelong antiarrhythmic drug therapy. The principal disadvantage is the risk for complications, which varies depending on the type of ablation procedure and skill of the operator.

ANESTHETIC CONSIDERATIONS

Catheter ablation was introduced into clinical practice in 1982. Initially, ablation was performed with direct electric shocks.[54] As a result of several advantages over direct current, radiofrequency ablation has replaced direct current ablation. These advantages include the absence of skeletal and cardiac muscle stimulation, minimal discomfort during delivery of energy, the possibility of performing the procedure in conscious patients, and the discrete nature of resulting lesions.[52]

Until recently, most cardiac ablation therapy for correction of arrhythmias could be performed under moderate sedation or monitored anesthesia care. In some of these cases, deep sedation may have been required as the case progressed. General anesthesia is now being employed routinely in most cases of cardiac ablation therapy due to patient anxiety and the extended period required for these procedures. General anesthesia may be implemented with standard American Society of Anesthesiologists monitors with adequate vascular access. Catheter ablation is the first-choice treatment for most cardiac arrhythmias. It is a safe treatment and is usually effective as a single procedure. Because it is curative in many patients, it is offered to all patients who would otherwise be committed to long-term drug therapy.

Future Trends

Correction of cardiac tachyarrhythmias has improved dramatically in the past two decades. Emphasis has shifted from pharmacologic therapy to nonpharmacologic therapy of tachyarrhythmias; this has led to a significant increase in the number of radiofrequency catheter ablations and defibrillator implantations. These developments were triggered by technologic advances that showed superiority of these procedures over the use of antiarrhythmic drugs.[55] As a result, treatment of supraventricular tachycardias and tachycardias involving accessory atrioventricular pathways will probably remain the domain of catheter ablation. The cure rate of patients treated with catheter ablation is very high. In addition, treatment of life-threatening ventricular tachyarrhythmia will remain in the domain of ICDs for the foreseeable future. The role of ICD therapy has been clearly defined with respect to prolongation of life and has been expanded to include primary prophylaxis of sudden death in high-risk populations.[56]

The demand for perioperative care in the electrophysiology suite, especially for those undergoing ablation procedures, has resurrected the use of high-frequency jet ventilation (HFJV) in recent years.[57] Although the use of HFJV in the electrophysiology suite is relatively new, studies have demonstrated improved outcomes and decreases in procedure time.[58] HFJV has been demonstrated to provide a more stable environment, especially in the posterior wall of the atrium. As a consequence, in the future HFJV use will increase and provide an attractive alternative to the conventional mode of ventilation during catheter ablation.[20,59] The anesthetic implications of this modality in the electrophysiology suite has recently been reviewed.[60]

As a result of these developments, the presence of an anesthesiology team will continue to increase in cardiology suites. Patients who are being cared for in these areas are sicker with significant comorbidities. The role of conscious sedation will continue to diminish in the performance of these procedures. These patients will require full monitoring and care under the direction of an anesthesiologist.

56 Anesthesia for Vascular Surgery

AHMED SHALABI and JOYCE CHANG

KEY POINTS

- Perioperative management of patients undergoing vascular surgery requires an understanding of the underlying pathophysiology of the specific vascular lesion.
- Major vascular surgery is particularly challenging to the anesthesiologist because these are high-risk operations in a patient population with a high prevalence of either overt or occult coronary artery disease, which is the leading cause of perioperative and long-term mortality after vascular surgery.
- Accurate clinical assessment of the pretest probability of significant coronary artery disease is necessary for prudent use and rational interpretation of preoperative cardiac testing.
- Guidelines on perioperative cardiovascular evaluation and care suggest that coronary intervention is rarely necessary to simply decrease the risk for surgery unless such intervention is indicated, irrespective of the preoperative context. Prophylactic coronary revascularization has not been shown to reduce perioperative or long-term morbidity after major vascular surgery. Medical therapy is the cornerstone for the management of coronary artery disease.
- Patients should take their usual cardiovascular medications throughout the perioperative period. Antiplatelet therapy requires special consideration and must be individualized to each patient.
- Prevention and treatment of perioperative myocardial ischemia require careful control of the determinants of myocardial oxygen supply and demand. ST-segment monitoring, particularly with computerized ST-segment analysis, should be used to detect myocardial ischemia during the perioperative period.
- Initiation of perioperative β-adrenergic blocker therapy has potential benefits and risks.
- All patients who require statin therapy on an ongoing basis should also receive statins in the perioperative period.
- The clinical usefulness of any intraoperative monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.
- Maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome after aortic surgery than is the choice of anesthetic drug or technique.
- The pathophysiology of aortic cross-clamping and unclamping is complex and depends on many factors, including the level of the cross-clamp, the extent of coronary artery disease and myocardial dysfunction, intravascular blood volume and distribution, activation of the sympathetic nervous system, and the anesthetic drugs and techniques.
- The degree of preoperative renal insufficiency is the strongest predictor of postoperative renal dysfunction.
- Endovascular aortic surgery has become an established, less invasive alternative to conventional open aortic repair. Endoleak, or the inability to obtain or maintain complete exclusion of the aneurysm sac from arterial blood flow, is a complication specific to endovascular aortic repair.
- The primary clinical utility of cerebral monitoring during carotid endarterectomy is to identify patients in need of carotid artery shunting; second, such monitoring is used to identify patients who may benefit from an increase in arterial blood pressure or change in surgical technique.
- Postoperative hypothermia is associated with many undesirable physiologic effects and may contribute to adverse cardiac outcome.

Preoperative Evaluation

COEXISTING DISEASE

Patients undergoing vascular surgery have a high incidence of coexisting disease, including diabetes mellitus, hypertension, renal impairment, and pulmonary disease, all of which should be assessed and, if possible, optimized before surgery. Because of the systemic nature of atherosclerotic disease, patients with vascular disease frequently have arterial disease affecting multiple vascular territories. Coronary artery disease (CAD) is the leading cause of perioperative mortality at the time of vascular surgery, and long-term survival after vascular procedures is significantly limited by the frequent occurrence of morbid cardiac events.[1] Less than 10% of patients who undergo vascular surgery have normal coronary arteries, and more than 50% have advanced or severe CAD. Unrecognized myocardial infarction (MI) (determined by wall motion abnormalities at rest in the absence of a history of MI) and silent myocardial ischemia (determined by stress-induced wall motion abnormalities in the absence of angina) often occur in vascular surgery patients (23% and 28%, respectively) and are associated with increased long-term mortality and adverse cardiac events.[2] Left ventricular systolic dysfunction (LVSD) is five times more common in patients with vascular disease than in matched controls.[3] It is not clear whether any specific category of vascular disease is associated with a greater likelihood of coexisting CAD. Some investigators have shown a similar incidence and severity of CAD in patients with aortic, lower extremity, and carotid disease. Others have shown that patients with lower extremity vascular disease are more likely to have significant CAD and to experience perioperative morbidity. Medical therapy is the cornerstone of the management of CAD.

PERIOPERATIVE AND LONG-TERM CARDIAC OUTCOMES

Preoperatively, the potential for MI and death in patients undergoing vascular surgery must be considered (Table 56.1). Nonfatal and fatal MIs are the most important and specific outcomes that determine perioperative cardiac morbidity. When multiple recent studies are pooled, the overall prevalence of perioperative MI and death is 4.9% and 2.4%, respectively. When outcomes are assessed over the long term (2 to 5 years), the prevalence of MI and death is 8.9% and 11.2%, respectively. This perioperative and long-term morbidity and mortality persist despite aggressive medical and surgical therapy.[4]

TABLE 56.1 Rates of Myocardial Infarction and Death in Patients Undergoing Vascular Surgery

Study	MI (%)	Death (%)	Comments
SHORT-TERM FOLLOW-UP (IN HOSPITAL OR 30-DAY)			
Ouyang et al.[5]	8	0	Small study
Raby et al.[6]	2.3	0.06	Aortic, lower extremity, carotid

MI, Myocardial infarction.

GUIDELINE-BASED APPROACH

A guideline-based approach to health care is relatively new and originated primarily in the United States. The American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) jointly produced guidelines in the area of cardiovascular disease for more than 2 decades. The ACC/AHA Task Force on Practice Guidelines published "Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery" in 1996. This evidence-based approach to perioperative evaluation and management was updated in 2002, 2007,[18] 2009,[19] and 2014.[20] A stepwise approach (simplified from the 2007 guidelines) to perioperative cardiac evaluation and care for noncardiac surgery is provided in Chapter 31. The authors emphasize that the purpose of the preoperative evaluation is not to give medical clearance but rather to perform an evaluation of the patient's current medical status; make recommendations concerning the evaluation, management, and risk for cardiac problems; and provide a clinical risk profile that the patient and caregivers can use in making treatment decisions that may influence perioperative and longer-term cardiac outcomes. The overriding theme of the perioperative guidelines is that intervention is rarely necessary to simply lower the risk associated with surgery unless such intervention is indicated, irrespective of the preoperative context. Thus, preoperative testing should not be performed unless it is likely to influence patient care. The particular challenge that the vascular surgery patient presents is emphasized throughout the document. Aspects of the updated guidelines and their evidence-based approach will be discussed throughout this chapter.

CARDIAC RISK ASSESSMENT

The preoperative cardiac assessment presents an opportunity to initiate and optimize pharmacologic management, perform appropriate diagnostic and therapeutic interventions, and adjust overall care to decrease not only perioperative risk but also long-term risks from cardiovascular events. The challenge for clinicians is to accurately assess risk for cardiac morbidity while maintaining a cost-effective, clinically relevant, and evidence-based strategy. The ACC/AHA stepwise approach considers vascular surgery distinct from other noncardiac surgical procedures and is reviewed in detail in Chapter 31. Only issues specific to vascular surgery are reviewed in this chapter.

After assessment of cardiac risk, the additional challenge exists of modifying perioperative management to reduce risk by adjusting or adding cardiac medications (e.g., β-adrenergic blocker), direct coronary intervention (e.g., percutaneous coronary intervention [PCI] or coronary artery bypass grafting [CABG]), modifying or intensifying perioperative management (e.g., invasive hemodynamic monitoring), or changing preoperative plans (e.g., performing endovascular aneurysm repair [EVAR] rather than open aortic repair). Coordination is essential among surgeons, anesthesiologists, and cardiologists, each of whom may have different criteria for risk assessment and different objectives for risk modification.

Clinical Risk Indices

Assessing cardiac risk in patients before vascular surgery is a controversial and difficult task. Although risk indices are a cost-effective screening method for determining which patients may require further cardiac evaluation (i.e., additional risk stratification with noninvasive technologies), the high pretest probability of CAD in vascular surgery patients makes the risk index somewhat less useful. Vascular surgery-specific indices have been recently developed to optimize the prediction of perioperative mortality[21] and cardiac morbidity[22] in patients undergoing elective and urgent vascular surgery. Risk indices do not provide specific risk prediction for individuals, but rather place patients in general risk categories, most commonly designated as low (cardiac risk generally <1%), intermediate (cardiac risk of 1% to 5%), or high (cardiac risk often >5%). Clinical risk variables identified by logistic regression in vascular surgery cohorts can be used along with noninvasive cardiac testing to optimize preoperative assessment of cardiac risk before vascular surgery. From the registry of the Coronary Artery Revascularization Prophylaxis (CARP) trial, the absence of multiple preoperative cardiac risk variables identifies patients with the best long-term survival after elective vascular surgery.[23]

Noninvasive Diagnostic Cardiac Testing

Accurate clinical assessment of the pretest probability of significant CAD is extremely important. In general, noninvasive cardiac testing before vascular surgery is best directed at patients considered to be at intermediate clinical risk. Such testing should not be undertaken if it is unlikely to alter patient management and should not be considered as a preliminary step leading to coronary revascularization. A revascularization procedure is rarely needed solely for the purpose of getting a patient through the perioperative period. Extensive cardiac evaluation before vascular operations can result in morbidity, delays, and patient refusal to undergo vascular surgery. A complete review of this subject is found in Chapter 31.

Cardiac Catheterization and Prophylactic Revascularization

The largest series on outcome in vascular surgery patients is that of Hertzer and colleagues[24] from the Cleveland Clinic. These investigators performed cardiac catheterization in 1000 consecutive patients scheduled to undergo peripheral vascular surgery (aortic aneurysm resection, carotid endarterectomy, and lower extremity revascularization). The incidence and severity of CAD were assessed according to the following classification: normal coronary arteries; mild-to-moderate CAD with no lesion exceeding 70% stenosis; advanced, compensated CAD with one or more lesions exceeding 70% stenosis but with adequate collateral circulation; severe, correctable CAD with more than 70% stenosis in one or more coronary arteries; and severe inoperable CAD with greater than 70% stenosis in one or more coronary arteries and severe distal disease or poor ventricular function. The most remarkable findings were that only 8.5% of patients had normal coronary arteries and 60% had advanced or severe coronary lesions (>70% stenosis). Even when CAD was not suspected by the clinical history, more than a third of patients had advanced or severe coronary lesions (Table 56.2).

TABLE 56.2 Results of Coronary Angiography in 1000 Patients with Peripheral Vascular Disease

	CLINICAL CAD					
	NONE		SUSPECTED		TOTAL	
Angiographic Classification	**No.**	**%**	**No.**	**%**	**No.**	**%**
Normal coronary arteries	64	14	21	4	85	8.5
Mild–to–moderate CAD	218	49	99	18	317	32
Advanced, compensated CAD	97	22	192	34	289	29
Severe, correctable CAD	63	14	188	34	251	25
Severe, inoperable CAD	4	1	54	10	58	5.8

CAD, Coronary artery disease.

Data from Hertzer NR, Beven EG, Young JR, et al. Coronary artery disease in peripheral vascular patients: a classification of 1000 coronary angiograms and results of surgical management. *Ann Surg*. 1984;199:223–233.

In the Hertzer series, patients with severe correctable CAD were offered CABG before their vascular surgery, patients with normal or mild-to-moderate CAD went directly to vascular surgery, and those with severe inoperable CAD were treated on an individual basis. Combined mortality rates over the immediate- and long-term (4.6-year follow-up) postoperative period are shown in Table 56.3.[17] Of the 216 patients who underwent coronary revascularization (CABG), 12 (5.5%) died after this surgery. This mortality rate is higher than that reported for patients undergoing CABG surgery without peripheral vascular disease (1% to 2%). Perhaps the risks associated with CABG should be seriously considered as part of the preoperative evaluation of these patients. When overall early and late mortality (>5 years) is considered, death occurred in 12% versus 26% of patients who did or did not undergo CABG. Although these data appear to support the beneficial effect of CABG on outcome, the mortality from CABG itself (5.5%) reduces its apparent benefits.

Two randomized clinical trials have been performed to determine the impact of prophylactic coronary artery revascularization on outcome after open aortic and lower extremity arterial vascular surgery.[4,25] Of the 5859 patients screened in the CARP trial, 41190 underwent coronary angiography based on a combination of clinical risk factors and noninvasive stress imaging data.[26] The incidence and severity of CAD on these angiograms were 43% of patients had one or more major coronary arteries with at least a 70% stenosis suitable for revascularization (and were randomized to either revascularization or no revascularization before vascular surgery); 31% had

TABLE 56.3 Perioperative and Late Cardiac Deaths after Peripheral Vascular Reconstruction in Patients Monitored over a 5-Year Period According to Coronary Angiographic Classification

CABG, Coronary artery bypass grafting; CAD, coronary artery disease.

Data from Hertzer NR, Young JR, Beven EG, et al. Late results of coronary bypass in patients with peripheral vascular disease. II. Five–year survival according to sex, hypertension, and diabetes. *Cleve Clin J Med*. 1987;54:15–23.

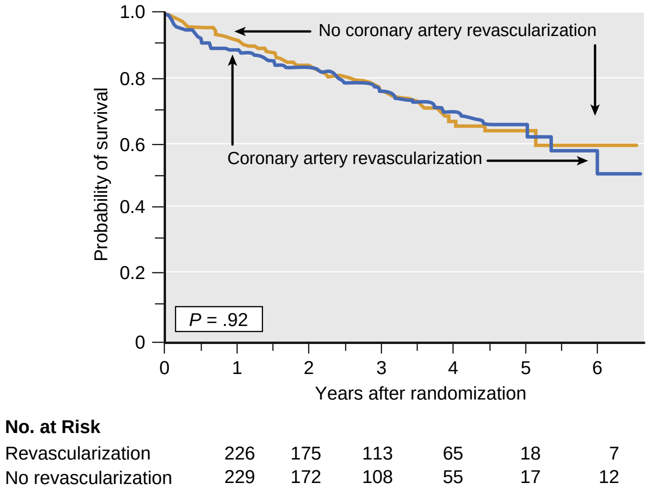

Fig. 56.1 Long-term survival in patients randomized to undergo coronary artery revascularization or no coronary artery revascularization before elective major vascular surgery (Coronary Artery Revascularization Prophylaxis trial). (From McFalls EO, Ward HB, Moritz TE, et al. Coronary-artery revascularization before elective major vascular surgery. *N Engl J Med.* 2004;351:2796–2804.)

nonobstructed coronary arteries; 18% had coronary stenosis considered unsuitable for revascularization; and 5% had left main coronary artery stenosis of 50% or more. The CARP trial showed that prophylactic revascularization (by CABG or PCI) was generally safe but did not improve long-term outcome after vascular surgery. Long-term mortality (2.7 years) was 22% in the revascularization group and 23% in the group considered inappropriate for revascularization (Fig. 56.1). Although the trial was not designed to test the short-term benefit of prophylactic revascularization, perioperative outcomes were not decreased, including death (3.1% vs. 3.4%) and MI (12% vs. 14%). The CARP trial results can be applied to most of the vascular surgery patients; however, they cannot be extrapolated to patients with unstable cardiac symptoms, left main coronary artery disease, aortic stenosis, or severe left ventricular dysfunction because these conditions excluded patients from study participation. The DECREASE-V trial 26 screened 1880 vascular surgery patients, 430 of whom with three or more clinical risk factors underwent noninvasive stress testing using stress-echo or perfusion imaging. Patients with extensive stress-induced ischemia (26%) were randomly assigned to revascularization or no revascularization. Coronary angiography showed two-vessel disease in 24%, three-vessel disease in 67%, and left main coronary artery disease in 8%. Prophylactic coronary revascularization (CABG or PCI) did not improve perioperative or long-term outcome (Table 56.4). The incidence of all-cause death or nonfatal MI at 30 days in patients who underwent revascularization or who did not was 43% versus 33%, respectively. The incidence of the composite end point at 1 year was similar, 49% versus 44%, respectively. As noted previously, this trial has come under scrutiny based on concerns of scientific misconduct by the principal investigator.

The lack of benefit of prophylactic coronary revascularization in the CARP and DECREASE-V trials is difficult to reconcile with the more favorable data from Hertzer and co-workers 25 and other studies (Coronary Artery Surgery Study [CASS][27] and Bypass Angioplasty Revascularization Investigation [BARI][28]). Clearly, issues are involved that go beyond critical coronary lesions; perhaps the current understanding of the pathophysiology of perioperative MI is incomplete. For example, perioperative MI may be caused by culprit lesions (i.e., vulnerable plaques with high likelihood of thrombotic complications) often located in coronary vessels *without* critical stenosis.[29] For this type of MI (atherothrombotic), perioperative strategies aimed at reducing potential triggers of coronary plaque destabilization and rupture may be more appropriate than those leading to coronary revascularization. Demand ischemia is likely the predominant cause of perioperative MI, which has been confirmed by a recent angiographic study.[30]

TABLE 56.4 Perioperative and Long-Term Patient Outcomes from the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE)-V—V TRIAL

	Revascularization No. (%)	No Revascularization No. (%)	HR (95% CI)	*P*-value

ASSESSMENT OF PULMONARY FUNCTION

Postoperative pulmonary complications are potentially serious in patients undergoing vascular surgery, with the most significant morbidity seen in patients undergoing open aortic procedures (see also Chapter 54). The most important pulmonary complications are atelectasis, pneumonia, respiratory failure, and exacerbation of underlying chronic disease. Given the prevalence of cigarette smoking in this population, chronic obstructive pulmonary disease (COPD) and chronic bronchitis are common and, when present, place the patient at increased risk for postoperative pulmonary complications. When clinical assessment suggests severe pulmonary compromise, pulmonary function tests may be useful in evaluating and optimizing respiratory function (see also Chapters 32 and 41). Preoperative analysis of arterial blood gases should be used to establish a baseline for postoperative comparison. Baseline hypercapnia (partial pressure of arterial carbon dioxide >45 mm Hg) indicates a more frequent risk for postoperative morbidity. Bronchodilator therapy may be indicated on the basis of results of pulmonary function tests, although the risk for β-adrenergic agonist–induced arrhythmia or myocardial ischemia also must be considered. Preoperative treatment with a short course of glucocorticoids (prednisone 40 mg/day for 2 days) may be helpful for patients with significant COPD or asthma. Evidence of pulmonary infection should be treated with appropriate antibiotics. Although improved pulmonary outcome with regional anesthesia is not clear, patients with significant pulmonary disease may benefit from epidural techniques. Use of these techniques in the postoperative period helps to avoid respiratory depression from systemic opiates (see also Chapter 81). Pulmonary complications in the postoperative period are difficult to avoid. Incentive spirometry and continuous positive airway pressure (CPAP) do provide benefit.[31] Given proper pulmonary care, even patients with severe pulmonary insufficiency, however, may undergo aortic surgery with acceptable morbidity and mortality outcomes.[32]

ASSESSMENT OF RENAL FUNCTION

Chronic renal disease is common in vascular surgery patients and is associated with an increased risk for death and cardiovascular disease (see also Chapters 30 and 42).[33] Chronic renal disease strongly predicts long-term mortality in patients with symptomatic lower extremity arterial occlusive disease irrespective of disease severity, cardiovascular risk, and concomitant treatment.[34] Cardiovascular disease is independently associated with a decline in renal function and the development of kidney disease.[35] Serum creatinine and creatinine clearance are used to assess renal function perioperatively. A preoperative serum creatinine level more than 2 mg/dL is an independent risk factor for cardiac complications after major noncardiac surgery.[36] Preoperative creatinine clearance less than 60 mL/min is an independent predictor of both short-term and long-term mortality after elective vascular surgery.[37] Perioperative β-adrenergic blocker[38] and statin[37] administration decrease risk for death in vascular surgery patients with renal impairment. Atherosclerotic disease in the abdominal aorta or renal arteries may compromise renal blood flow and renal function. Conversely, renal artery stenosis causes hypertension through renin-induced and angiotensin-induced vasoconstriction. Hypertension itself may cause renal insufficiency or failure. Diabetic nephropathy is also common (see also Chapter 32). Superimposed on baseline abnormalities in renal function are the preoperatively and intraoperatively administered angiographic dyes, which are directly nephrotoxic. Renal ischemia occurs with interruption of renal blood flow from aortic cross-clamping. Even with infrarenal aortic cross-clamps, renal blood flow may decrease despite normal systemic arterial blood pressure and cardiac output. Embolic plaque can be showered into the renal arteries, especially when suprarenal aortic cross-clamps are applied and released. Fluctuations in intravascular volume and cardiac output can compromise renal perfusion during the intraoperative and postoperative periods. In one series of more than 500 patients, the prevalence of acute renal failure was 7% after abdominal aortic reconstruction.

PERIOPERATIVE β-ADRENERGIC BLOCKER THERAPY

Perioperative β-adrenergic blocker therapy is an important and controversial topic, particularly in patients undergoing vascular surgery, and is reviewed more fully in Chapters 31 and 32. Patients receiving chronic β-adrenergic blocker therapy should continue taking β-adrenergic blockers throughout the perioperative period. However, β-adrenergic blockers should not be used as the initial or primary treatment of tachycardia caused by perioperative events, such as hypovolemia, anemia, pain, or infection, because these conditions require prompt treatment of the underlying cause. Treatment of tachycardia caused by the sympathetic stimulation associated with surgical stress should be considered in high-risk patients, particularly those with known ischemic potential (i.e., ischemia on preoperative testing). Hypotension and bradycardia should be avoided. Acute initiation of large-dose β-adrenergic blockade in the perioperative period should be avoided. If a decision is made to initiate β-blocker treatment in the perioperative period to reduce cardiac risk, the safest approach may be to initiate therapy with a small dose and titrate to effect over a 7- to 10-day period before the planned surgery. Perioperative β-adrenergic blocker therapy can decrease the number of patients referred for preoperative cardiac testing. However, such testing should not be eliminated, and its risk-to-benefit ratio should be carefully assessed.

PERIOPERATIVE STATIN THERAPY

In addition to their lipid-lowering properties, statins have beneficial anti-inflammatory, plaque-stabilizing, and antioxidant effects (see also Chapter 32). Over the last decade, statin use has emerged as a promising strategy for the prevention of perioperative cardiovascular complications in patients undergoing vascular surgery.[39] This approach is supported by the double-blind, placebo-controlled DECREASE-III trial. Unfortunately, controversy exists regarding this trial because of scientific misconduct identified by a recent investigation by Erasmus University.[40] Statin use can help preserve renal function after aortic surgery and improve graft patency after lower extremity bypass surgery. Although current guidelines recommend the use of statins in all patients with peripheral arterial disease, the optimal timing and dosing of statins for perioperative use have not been established.

PERIOPERATIVE DUAL ANTIPLATELET THERAPY

The timing of noncardiac surgery in patients treated with coronary stents with the risk of stent thrombosis if the dual antiplatelet therapy (DAPT) is discontinued versus the risk of increased intraoperative bleeding if DAPT is continued. [20,41] Previous recommendations regarding the duration of DAPT and timing of noncardiac surgeries were based on observations of those treated with first-generation stents. Currently, used newer generations of stents, particularly the newer drug eluting stents (DES), have lower risk of in-stent thrombosis and require a shorter minimum duration of DAPT.[42] The safety of treating patients with newer generation DES treated for shorter durations of DAPT (3 to 6 months) has been demonstrated in a meta-analysis of four trials.[43] Also, in the PARIS (Patterns of Nonadherence to Antiplatelet Regimens in Stented Patients) registry, interruption of DAPT based on the physician judgment in patients undergoing surgery at any point did not affect the risk of major cardiac events.[44] Hence, the ACC/AHA guidelines were changed in 2016 to reflect those changes (see Chapters 31 and 32).[45]

Abdominal Aortic Reconstruction

Anesthesia for conventional abdominal aortic reconstruction requires an understanding of the pathophysiology, extensive knowledge of the surgical procedure, the ability to interpret sophisticated hemodynamic data, and skillful pharmacologic control and manipulation of hemodynamics. Preoperative and intraoperative communication with the surgical team is essential. All open operative procedures on the abdominal aorta and its major branches require large incisions and extensive dissection, clamping and unclamping of the aorta or its major branches, varying duration of organ ischemia-reperfusion, significant fluid shifts and temperature fluctuations, and activation of neurohumoral and inflammatory responses. The major objectives of surgical treatment of the aorta are to relieve symptoms, reduce the frequency of associated complications, and in the case of aortic aneurysm, prevent rupture. Over the last two decades, the growth and development of catheter-based technology for the treatment of peripheral arterial disease have generated tremendous interest for less invasive methods to treat aortic disease.

Endovascular aortic aneurysm repair (discussed later) has become an established, less invasive alternative to conventional open repair, and its use has expanded to more than 75% of elective repairs and 30% of rupture repairs.[46] The endovascular field continues to evolve rapidly with new devices, innovations, and indications for aortic disease.

NATURAL HISTORY AND SURGICAL MORTALITY

Abdominal Aortic Aneurysm

Abdominal aortic aneurysms (AAAs) occur frequently in elderly men, with an incidence approaching 8% (see also Chapter 65). Increasing age, smoking, family history of AAA, and atherosclerotic disease are established risk factors. Although the prevalence is less frequent in women, the risk factors for AAA resemble those in men. More than 30,000 deaths result from rupture of AAAs each year in the United States.[47] The number of hospital discharges each year with the first diagnosis of aortic aneurysm is nearly 70,000. Approximately 40,000 patients undergo repair of AAA each year in the United States, at a cost likely to exceed a billion dollars. The incidence of AAA appears to be increasing and is age- and gender-dependent.

AAA is a multifactorial disease associated with aortic aging and atherosclerosis. Although no unified concept of pathogenesis exists, genetic, biochemical, metabolic, infectious, mechanical, and hemodynamic factors may contribute to the development of AAA disease. Adventitial elastin degradation (elastolysis), a hallmark of AAA formation, may be the primary event. Chronic inflammation plays a fundamental role in the destruction of connective tissue in the aortic wall. Concomitant aortoiliac occlusive disease is present in approximately 20% to 25% of patients with AAA. Approximately 5% of patients undergoing abdominal aortic resection have inflammatory aneurysms. Rare causes of AAA disease include trauma, mycotic infection, syphilis, and Marfan syndrome.

Most AAAs are detected incidentally when imaging is performed for other reasons or through screening programs. The natural history of AAA disease is progressive enlargement and ultimate rupture and death. The diameter and rate of expansion of asymptomatic AAAs are the best predictors of the risk for rupture. Current guidelines emphasize that it is not possible to recommend a single threshold diameter for operative intervention that can be generalized to all patients. Yet, elective repair should be undertaken in all patients with AAA 6 cm or larger in diameter. Although some controversy exists regarding elective AAA repair when its diameter is in the 5.5- to 5.9-cm range, the risk for rupture of a 5.5-cm aneurysm (per year) is equal to or greater than the risk for perioperative mortality, and thus surgical repair is indicated. The 1-year incidence of probable rupture in patients refusing or unfit for elective repair is 9.4%, 10.2%, and 32.5% for aneurysms 5.5 to 5.9 cm, 6.0 to 6.9 cm, and 7.0 cm or greater, respectively.[48] Over 90% of AAAs are less than the current threshold (5.5 cm) for surgical repair at the time of detection. Randomized controlled trials in patients with AAAs 4.0 to 5.5 cm in diameter have provided important insight into the natural history of small asymptomatic aortic aneurysms.[49] Four trials have demonstrated that surveillance of small aneurysms (4.0 to 5.5 cm) is a safe management option and that early repair (open or endovascular surgery) did not result in any long-term survival benefit. Surgical repair is often considered if small aneurysms become symptomatic or expand more than 0.5 cm in a 6-month period. Although significant interest exists in medical treatment (e.g., antibiotics, β-adrenergic blockers, statins) to delay or reverse expansion of small aneurysms, evidence for a protective effect is limited.[50] Aneurysms less than 4.0 cm in diameter are thought to be relatively benign in terms of rupture and expansion.

Perioperative mortality from elective resection of infrarenal AAAs has progressively declined from 18% to 20% during the 1950s, 6% to 8% in the mid-1960s, 5% to 6% in the early 1970s, and 2% to 4% in the 1980s, at which time it plateaued. A publication of data from 1000 consecutive elective open infrarenal abdominal aneurysm repairs over a 15-year period reported a perioperative mortality rate of 2.4%.[51] Hertzer and co-workers[52] reported a mortality rate of 1.2% for 1135 consecutive elective open infrarenal abdominal aortic repairs at the Cleveland Clinic. This single-center mortality rate is considerably less than the mortality rates of 5.6% to 8.4% reported from large national data sets. These more frequent mortality rates on the national level suggest that all the technologic and treatment advances over the last 2 decades have not had an impact on outcomes of patients requiring open AAA repair. Regionalization of patient care and endovascular treatments currently hold the most promise for improvement in operative mortality.

For ruptured AAAs, perioperative mortality has not changed significantly over the last 4 decades and remains nearly 50%, with few exceptions. Including patients with rupture who die before reaching a hospital, the overall mortality rate after rupture may very well exceed 90%.

The long-term durability of open infrarenal AAA repair is excellent and well established. The incidence of late graft complications is infrequent (0.4% to 2.3%). Postoperative survival rates after repair of non-ruptured AAA are 92% at 1 year and 67% at 5 years.

Aortoiliac Occlusive Disease

The infrarenal aorta and the iliac arteries are two of the most common sites of chronic atherosclerosis. Because of the diffuse and progressive nature of aortoiliac atherosclerosis, plaque enlargement may reduce blood flow to the lower extremities below a critical level and result in symptoms of ischemia. Unlike patients with aortic aneurysmal disease, patients undergo surgery for aortoiliac occlusive disease only if they are symptomatic. Surgical intervention is indicated for disabling intermittent claudication and limb-threatening ischemia. Intervention is directed toward restoring peripheral pulsatile circulation to relieve claudication and toward preventing amputation. Patients with localized aortoiliac occlusive disease typically have claudication because collateral circulation adequate to prevent critical lower extremity ischemia usually exists. Perioperative mortality is lower in patients undergoing aortoiliac reconstruction than in those undergoing abdominal aortic surgery.

Therapeutic options for managing aortoiliac occlusive disease include anatomic or direct reconstruction (i.e., aortobifemoral bypass), extra-anatomic or indirect bypass grafts (i.e., axillofemoral bypass), and catheter-based endoluminal techniques (i.e., percutaneous transluminal angioplasty [PTA] with or without stent insertion). Aortobifemoral bypass is viewed as the gold standard in treating aortoiliac occlusive disease. Extra-anatomic bypass grafts are generally reserved for specific indications, usually patients with infection, failure of previous reconstruction, or prohibitive risk. Reduced long-term patency and inferior functional results are frequently the trade-off for lower perioperative morbidity and mortality. Catheter-based endoluminal techniques, such as PTA, are used for relatively localized disease and may be reasonable alternatives to aortobifemoral bypass in 10% to 15% of patients with aortoiliac occlusive disease.

Renal and Visceral Arterial Insufficiency

Atherosclerosis is the most common cause of renal artery stenosis. Occlusive lesions are located almost exclusively in the proximal segment and orifice of the renal artery and are usually an extension of aortic atherosclerosis. Fibromuscular dysplasia is an important, but less common, cause of renal artery stenosis and most frequently involves the distal two thirds of the renal arteries. Hemodynamically significant renal artery stenosis may cause hypertension by activation of the renin-angiotensin-aldosterone system, and bilateral involvement may result in renal failure. Patients with renovascular hypertension frequently have poorly controlled hypertension despite maximal medical therapy. These patients often have severe bilateral renal artery stenosis and may have recurrent congestive heart failure or flash pulmonary edema. Indications for intervention include control of hypertension and salvage of renal function.

Operative interventions include aortorenal bypass, extra-anatomic bypass (hepatorenal or splenorenal bypass), or transaortic endarterectomy. Suprarenal or supraceliac aortic cross-clamping is frequently required for open operative interventions. PTA with stenting of the renal artery is used as the first-line treatment in selected patients.

Stenosis at the origin of the celiac and mesenteric arteries occurs as a result of extension of aortic atherosclerosis. The inferior mesenteric artery is by far the most commonly involved, followed by the superior mesenteric artery and the celiac artery.

Occlusion of a single vessel rarely causes ischemic symptoms because of the extensive nature of visceral collateralization. However, occlusion or significant stenosis of any two vessels may compromise collateral flow sufficiently to give rise to chronic visceral ischemia. Operative repair of visceral artery stenosis is reserved for symptomatic patients. Operative interventions include transaortic endarterectomy and bypass grafts, which frequently require supraceliac aortic cross-clamping. Mortality rates for such procedures range from 7% to 18%. To avoid the high mortality associated with open repair, PTA with stenting has increasingly been applied in patients with chronic visceral ischemia. Acute visceral artery occlusion can be caused by an embolus or, less commonly, by thrombosis. To avoid the extremely high mortality associated with acute visceral ischemia, diagnosis and surgical intervention must occur before gangrene of the bowel develops.

AORTIC CROSS CLAMPING

The pathophysiology of aortic cross-clamping is complex and depends on many factors, including level of the cross-clamp, status of the left ventricle, degree of periaortic collateralization, intravascular blood volume and distribution, activation of the sympathetic nervous system, and anesthetic drugs and techniques. Most abdominal aortic reconstructions require clamping at the infrarenal level. However, clamping at the suprarenal and supraceliac levels is required for suprarenal aneurysms and renal or visceral reconstructions and is frequently necessary for juxtarenal aneurysms, inflammatory aneurysms, and aortoiliac occlusive disease with proximal extension. These higher levels of aortic occlusion have a significant impact on the cardiovascular system, as well as on other vital organs rendered ischemic or hypoperfused. Ischemic complications may result in renal failure, hepatic ischemia and coagulopathy, bowel infarction, and paraplegia. With EVAR now common, an increasing proportion of patients undergoing open repair have anatomically complex aneurysms, many of which require suprarenal cross- clamping.[53]

Hemodynamic and Metabolic Changes

The hemodynamic and metabolic changes associated with aortic cross-clamping are summarized in Box 56.1. The magnitude and direction of these changes are complex, dynamic, and vary among experimental and clinical studies. However, several important factors must be considered (Box 56.2). The systemic cardiovascular consequences of aortic cross-clamping can be dramatic, depending primarily on the level at which the cross-clamp is applied. Arterial hypertension above the clamp and arterial hypotension below the clamp are the most consistent components of the hemodynamic response to aortic cross-clamping at any level. The increase in arterial blood pressure above the clamp is primarily due to the sudden increase in impedance to aortic blood flow and the resultant increase in systolic ventricular wall tension or afterload. However, factors such as myocardial contractility, preload, blood volume, and activation of the sympathetic nervous system also may be important.[54] Cross-clamping of the aorta at or above the diaphragm results in the most profound increases in arterial blood pressure unless diverting circulatory support or IV vasodilators are used. Changes in cardiac output and filling pressure with aortic cross-clamping are not consistent and require an integrated approach in understanding

BOX 56.1 Physiologic Changes With Aortic Cross-Clamping* and Therapeutic Interventions

Hemodynamic Changes

↑ Arterial blood pressure above the clamp
↓ Arterial blood pressure below the clamp
↑ Segmental wall motion abnormalities
↑ Left ventricular wall tension
↓ Ejection fraction
↓ Cardiac output[†,‡]
↓ Renal blood flow
↑ Pulmonary occlusion pressure
↑ Central venous pressure
↑ Coronary blood flow

Metabolic Changes

↓ Total body oxygen consumption
↓ Total body carbon dioxide production
↑ Mixed venous oxygen saturation
↓ Total body oxygen extraction
↑ Epinephrine and norepinephrine
Respiratory alkalosis
Metabolic acidosis

Therapeutic Interventions

- Afterload reduction
  - Sodium nitroprusside
  - Inhalational anesthetics
  - Amrinone
  - Shunts and aorta-to-femoral bypass
- Preload reduction
  - Nitroglycerin
  - Controlled phlebotomy
  - Atrial-to-femoral bypass
- Renal protection
  - Fluid administration
  - Distal aortic perfusion techniques
  - Selective renal artery perfusion
  - Mannitol
  - Drugs to augment renal perfusion
- Other
  - Hypothermia
  - ↓ Minute ventilation
  - Sodium bicarbonate

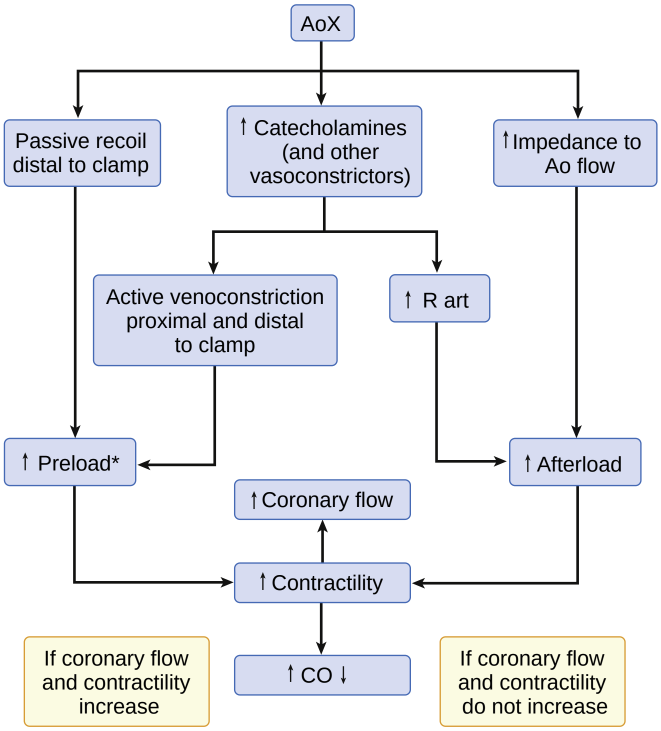
*These changes are of greater significance with longer duration of cross-clamping and with more proximal cross-clamping.

[†] Cardiac output may increase with thoracic cross-clamping.

[‡] When ventilatory settings are unchanged from pre-clamp levels.

BOX 56.2 Factors That May Influence the Magnitude and Direction of Physiologic Changes Occurring With Aortic Cross-Clamping

Level of aortic cross-clamp
Species differences
Anesthetic agents and techniques
Use of vasodilator therapy
Use of diverting circulatory support
Degree of periaortic collateralization
Left ventricular function
Status of the coronary circulation
Volume status
Neuroendocrine activation
Duration of aortic cross-clamp
Body temperature



AoX
Passive recoil distal to clamp
↑ Catecholamines (and other vasoconstrictors)
↑ Impedance to Ao flow
Active venoconstriction proximal and distal to clamp
↑ R art
↑ Preload*
↑ Afterload
↑ Coronary flow
↑ Contractility
If coronary flow and contractility increase
↑ CO ↓
If coronary flow and contractility do not increase

Fig. 56.2 Systemic hemodynamic response to aortic cross-clamping. Preload *(asterisk)* does not necessarily increase with infrarenal clamping. Depending on splanchnic vascular tone, blood volume can be shifted into the splanchnic circulation and preload will not increase. *Ao*, Aortic; *AoX*, aortic cross-clamping; *CO*, cardiac output; *R art*, arterial resistance.

TABLE 56.5 Percent Change in Cardiovascular Variables on Initiation of Aortic Occlusion

	PERCENT CHANGE AFTER OCCLUSION		
Cardiovascular Variable	**Supraceliac**	**Suprarenal-Infraceliac**	**Infrarenal**
Mean arterial blood pressure	54	5*	2*
Pulmonary capillary wedge pressure	38	10*	0*
End-diastolic area	28	2*	9*
End-systolic area	69	10*	11*
Ejection fraction	−38	−10*	−3*
Patients with wall motion abnormalities	92	33	0

*Statistically different ($P < .05$) from group undergoing supraceliac aortic occlusion.

From Roizen MF, Beaupre PN, Alpert RA, et al. Monitoring with two-dimensional transesophageal echocardiography: comparison of myocardial function in patients undergoing supraceliac, suprarenal-infraceliac, or infrarenal aortic occlusion. *J Vasc Surg*. 1984;1:300–305.

the direction and magnitude of such changes (Fig. 56.2). Cross-clamping of the proximal descending thoracic aorta increases mean arterial, central venous, mean pulmonary arterial, and pulmonary capillary wedge pressure by 35%, 56%, 43%, and 90%, respectively, and decreases the cardiac index by 29%.[55] Heart rate and left ventricular stroke work are not significantly changed. Supraceliac aortic cross-clamping increases mean arterial pressure by 54% and pulmonary capillary wedge pressure by 38%.[56] Ejection fraction, as determined by two-dimensional echocardiography, decreases by 38%. Despite normalization of systemic and pulmonary capillary wedge pressure with anesthetic agents and vasodilator therapy, supraceliac aortic cross-clamping causes significant increases in left ventricular end-systolic and end-diastolic area (69% and 28%, respectively), as well as wall motion abnormalities indicative of ischemia in 11 of 12 patients (Table 56.5). Aortic cross- clamping at the suprarenal level causes similar but smaller cardiovascular changes and clamping at the infrarenal level is associated with only minimal changes and no wall motion abnormalities.

The marked increases in ventricular filling pressure (preload) reported with high aortic cross-clamping have been attributed to increased afterload and redistribution of blood volume, which is of prime importance during thoracic aortic cross-clamping. The splanchnic circulation, an important source of functional blood volume reserve, is central to this hypothesis. The splanchnic organs contain nearly 25% of the total blood volume, nearly two thirds (>800 mL) of which can be autotransfused from the highly compliant venous vasculature into the systemic circulation within seconds.[57] Primarily because of smaller splanchnic venous capacitance, blood volume is redistributed from vascular beds distal to the clamp to the relatively noncompliant vascular beds proximal to the clamp (Fig. 56.3). Both passive and active mechanisms lower splanchnic venous capacitance with thoracic aortic cross-clamping. Cross-clamping the aorta above the splanchnic system dramatically reduces splanchnic arterial flow, which produces a significant reduction in pressure within the splanchnic capacitance vessels.[58] This decreased pressure allows the splanchnic veins to passively recoil and increase venous return to the heart and blood volume proximal to the clamp. Thoracic aortic cross-clamping also results in significant increases in plasma epinephrine and norepinephrine, which may enhance venomotor tone both above and below the clamp. The splanchnic veins are highly sensitive to adrenergic stimulation. The major effect of catecholamines on the splanchnic capacitance vessels is venoconstriction, which actively forces out splanchnic blood, reduces splanchnic venous capacitance, and increases venous return to the heart.[58]

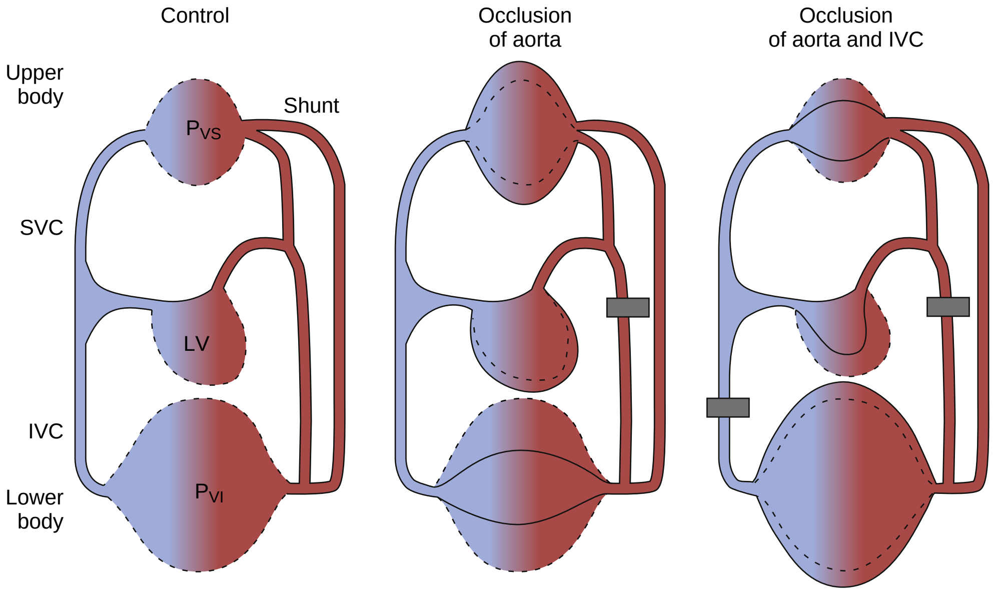


Fig. 56.3 Schematic drawing of the circulation. Compliant regions *(dashed lines)* of the upper and lower part of the body and end-diastolic volumes of the left ventricle in control state *(left panel)* are shown after occlusion of the aorta alone *(middle panel)* and combined occlusion of the aorta and inferior vena cava *(right panel)*. *IVC*, Inferior vena cava; *LV*, left ventricle; *PVS and PVI*, pressure in compliant regions of the upper and lower body, respectively; *Shunt*, physiologic shunt; *SVC*, superior vena cava.

Several animal studies support the blood volume redistribution hypothesis. Cross-clamping the thoracic aorta in dogs results in marked increases in mean arterial pressure and end-diastolic left ventricular pressure (84% and 188%, respectively) and no significant change in stroke volume.[59] In this same experimental model, simultaneous cross-clamping of the thoracic aorta and the inferior vena cava resulted in no significant change in mean arterial pressure or preload (see Fig. 56.3). Stroke volume was reduced by 74%. By transfusing blood (above the clamps) during this period of simultaneous clamping, the authors reproduced the hemodynamic effect of thoracic aortic cross-clamping alone. This study also demonstrated that thoracic aortic cross-clamping is associated with a significant and dramatic increase (155%) in blood flow above the level of the clamp whereas no change in blood flow occurred with simultaneous aortic and inferior vena cava clamping. In other animal models, the proximal aortic hypertension and increased central venous pressure (CVP) occurring after thoracic aortic cross-clamping were completely reversed by phlebotomy.[60] Aortic cross-clamping at the thoracic and suprarenal levels in dogs both resulted in proximal aortic hypertension, but only occlusion at the thoracic level increased central venous pressure.[61] In this study, thoracic aortic occlusion increased blood volume in organs and tissues proximal to the clamp whereas no such increase occurred with suprarenal aortic cross-clamping. These experimental data strongly support the hypothesis of blood volume redistribution during aortic cross-clamping and help explain the marked differences in hemodynamic responses observed after aortic cross-clamping at different levels.[56]

Afterload-dependent increases in preload also occur with aortic cross-clamping, usually in the setting of impaired myocardial contractility and reduced coronary reserve. The impaired left ventricle may respond to increased afterload with an increase in end-systolic volume and a concomitant reduction in stroke volume (afterload mismatch). The reduction in stroke volume may be due to limited preload reserve, myocardial ischemia, or inability of the heart to generate a pressure-induced increase in contractility (the Anrep effect). If right ventricular function remains normal, the pre-clamp right ventricular stroke volume added to the increased left ventricular end-systolic volume results in left ventricular dilation and elevated end-diastolic volume. If corrective measures are not undertaken, overt left ventricular overload may result, with severe peripheral organ dysfunction and pulmonary edema.

Most clinical studies indicate that cardiac output decreases with thoracic aortic cross-clamping (without vasodilator therapy or diverting circulatory support), whereas most animal studies show no significant change or an increase in cardiac output.

However, the status of the left ventricle clearly plays a major role. Whereas a normal intact heart can withstand large increases in volume without significant ventricular distention or dysfunction, an impaired heart with reduced myocardial contractility and coronary reserve may respond to such increase in volume conditions with marked ventricular distention as a result of acute left ventricular dysfunction and myocardial ischemia. Although impaired myocardial contractility and reduced coronary reserve are rare in animal experiments, such disorders are frequent in the elderly population undergoing aortic reconstruction. The increase in ventricular loading conditions seen with thoracic and supraceliac cross-clamping[55,56] in the clinical setting may increase left ventricular wall stress (afterload), with resultant acute deterioration of left ventricular function and myocardial ischemia.

Impaired subendocardial perfusion caused by high intramyocardial pressure may be the cause of wall motion abnormalities and changes in ejection fraction. Reflex mechanisms causing immediate feedback inhibition may also explain the reduction in cardiac output with aortic cross-clamping. For example, baroreceptor activation resulting from increased aortic pressure should depress the heart rate, contractility, and vascular tone. Thoracic aortic cross-clamping with the use of vasodilator therapy to normalize ventricular loading conditions maintains or increases cardiac output.[65] The metabolic effects of aortic cross-clamping are summarized in Box 56.1. Cross-clamping of the thoracic aorta decreases total-body O2 consumption by approximately 50%. For reasons that are unclear, O2 consumption decreases in tissues above the clamp. In clinical studies, increased mixed venous O2 saturation occurs with aortic cross-clamping above the celiac axis. This increase in mixed venous O2 saturation may be explained by a reduction in O2 consumption that exceeds the reduction in cardiac output, thus decreasing total body O2 extraction. Central hypervolemia and increased arteriovenous shunting in tissues proximal to the aortic clamp may play a role in reducing total body O2 extraction. Arterial blood pressure, blood flow, and O2 consumption distal to a thoracic aortic cross-clamp decrease by 78% to 88%, 79% to 88%, and 62%, respectively, from baseline values before clamping. Blood flow through tissues and organs below the level of aortic occlusion is dependent on perfusion pressure and is independent of cardiac output. Administration of sodium nitroprusside to maintain proximal aortic pressure above the cross-clamp at pre-clamp levels has been shown to further reduce arterial pressure distal to the clamp by 53%. As discussed later, these data have significant implications regarding vital organ protection during aortic cross-clamping.

The cardiovascular response to infrarenal aortic cross-clamping is less significant than with high aortic cross-clamping (see Table 56.5). Although several clinical reports have noted no significant hemodynamic response to infrarenal cross-clamping, the hemodynamic response generally consists of increases in arterial pressure (7% to 10%) and systemic vascular resistance (20% to 32%), with no significant change in heart rate. Cardiac output is most consistently decreased by 9% to 33%. Reported changes in ventricular filling pressure have been inconsistent. Blood volume redistribution may affect preload with infrarenal aortic cross-clamping (see Fig. 56.3). In this situation, blood volume below the clamp shifts to the compliant venous segments of the splanchnic circulation above the clamp, thereby dampening the expected increase in preload. The preload changes with infrarenal aortic cross-clamping also may depend on the status of the coronary circulation. Patients with severe ischemic heart disease responded to infrarenal aortic cross-clamping with significantly increased central venous (35%) and pulmonary capillary (50%) pressure, whereas patients without CAD had decreased filling pressure. Echocardiographically detected segmental wall motion abnormalities occur in up to 30% of patients during infrarenal aortic reconstruction, with over 60% occurring at the time of aortic cross-clamping. Patients with aortoiliac occlusive disease may have less hemodynamic response to infrarenal aortic cross-clamping than do patients with AAA disease, perhaps as a result of more extensive periaortic collateral vascularization.

RENAL FUNCTION AND PROTECTION

Preservation of renal function is highly important during aortic reconstructive surgery. Acute renal failure occurs in approximately 3% of patients undergoing elective infrarenal aortic reconstruction, and mortality resulting from postoperative acute renal failure is more frequent than 40%. Despite significant improvements in the perioperative care of these patients, the frequent incidence of morbidity and mortality resulting from acute renal failure has remained largely unchanged over the last several decades. Most of the morbidity associated with significant postoperative renal dysfunction is nonrenal.

The adequacy of renal perfusion “cannot” be assumed by urine output. Although urine output is closely monitored and often augmented during aortic surgery, intraoperative urine output does not predict postoperative renal function. Procedures requiring aortic cross-clamping above the renal arteries dramatically reduce renal blood flow. Experimental studies report an 83% to 90% reduction in renal blood flow during thoracic aortic cross-clamping. Infrarenal aortic cross-clamping in humans is associated with a 75% increase in renal vascular resistance, a 38% decrease in renal blood flow, and a redistribution of intrarenal blood flow toward the renal cortex. These rather profound alterations in renal hemodynamics occurred despite no significant change in systemic hemodynamics, and they persisted after unclamping. The sustained deterioration in renal perfusion and function during and after infrarenal aortic cross-clamping has been attributed to renal vasoconstriction, but the specific pathophysiologic process remains unknown. Renal sympathetic blockade with epidural anesthesia to a T6 level does not prevent or modify the severe impairment in renal perfusion and function that occurs during and after infrarenal aortic cross-clamping. Although plasma renin activity is increased during aortic cross-clamping, pretreatment with converting enzyme inhibitors before infrarenal aortic cross-clamping does not attenuate the decreased renal blood flow and glomerular filtration rate. Other mediators, such as plasma endothelin, myoglobin, and prostaglandins, may contribute to the decreased renal perfusion and function after aortic cross-clamping.

Acute tubular necrosis accounts for nearly all the renal dysfunction and failure after aortic reconstruction. The degree of preoperative renal insufficiency remains the strongest predictor of postoperative renal dysfunction. In addition to aortic cross-clamping-induced reductions in renal blood flow, ischemic reperfusion injury, intravascular volume depletion, embolization of atherosclerotic debris to the kidneys, and surgical trauma to the renal arteries all contribute to renal dysfunction.

Mannitol, loop diuretics, and dopamine are used clinically to preserve renal function during aortic surgery. Significant controversy exists regarding the use of these drugs, as well as the mechanisms by which they may offer a protective effect. Although not proved, pharmacologic “protection” before aortic cross-clamping is believed to be beneficial and is therefore given. The use of mannitol 12.5 g/70 kg to induce osmotic diuresis before aortic cross-clamping is ubiquitous in clinical practice. Mannitol improves renal cortical blood flow during infrarenal aortic cross-clamping and reduces ischemia-induced renal vascular endothelial cell edema and vascular congestion. Other mechanisms by which mannitol may be beneficial include acting as a scavenger of free radicals, decreasing renin secretion, and increasing renal prostaglandin synthesis. Loop diuretics and low-dose dopamine (1 to 3 μg/kg/min) are used to protect the kidneys from aortic cross-clamp-induced injury by increasing renal blood flow and urine output intraoperatively. Routine use of these drugs is common for patients with preoperative renal insufficiency and for procedures requiring suprarenal aortic cross-clamping. Intraoperative use of these drugs requires increased surveillance of intravascular volume and electrolytes during the postoperative period. Therapy with these drugs could actually be harmful because of hypovolemia and resultant renal hypoperfusion. In addition, dopamine's positive inotropic and chronotropic activity may cause tachycardia and increase myocardial O2 consumption in patients with limited coronary reserve.

Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some promise as a renoprotective drug. However, its role in the prevention of renal dysfunction after aortic surgery is not known. Statin use is associated with preserved renal function after aortic surgery requiring suprarenal aortic cross-clamping.[63] Remote ischemic preconditioning reduces the incidence of renal impairment after open aortic surgery.[64] Optimal systemic hemodynamics, including maintenance of intravascular volume and hematocrit, is generally considered the most effective means of renal protection during and after aortic cross-clamping. The goal is to achieve a preload adequate to allow the left ventricle to cope with cross-clamping-induced changes in contractility and afterload while maintaining cardiac output. However, in providing such therapy, excessive intravascular volume should be avoided because it may lead to inappropriate increases in preload or pulmonary edema in patients with decreased myocardial reserve.

THERAPEUTIC STRATEGIES

Patients with preexisting impaired ventricular function and reduced coronary reserve are most vulnerable to the stress imposed on the cardiovascular system by aortic cross-clamping. Rational therapeutic strategies to prevent the deleterious effect of aortic cross-clamping primarily include measures to reduce afterload and maintain a normal preload and cardiac output. Vasodilators, positive and negative inotropic drugs, and controlled intravascular volume depletion (i.e., phlebotomy) may be used selectively.

Patients with impaired ventricular function requiring supraceliac aortic cross-clamping are the most challenging. Myocardial ischemia, reflecting an unfavorable balance between myocardial O2 supply and demand, may result from the hemodynamic consequences of aortic cross-clamping. Controlled (i.e., slow clamp application) supraceliac aortic cross-clamping is important to avoid abrupt and extreme stress on the heart. Both afterload and preload reduction are often required. Afterload reduction, most commonly accomplished with the use of sodium nitroprusside or clevidipine (predominantly arteriolar dilators), is necessary to unload the heart and reduce ventricular wall tension. In a large series of patients requiring cross-clamping of the descending thoracic aorta, stable left ventricular function was maintained with sodium nitroprusside during cross-clamping. Sodium nitroprusside most likely allowed adequate intravascular volume before unclamping, which resulted in stable unclamping hemodynamics. A normal preload is equally important and involves careful IV fluid titration and vasodilator administration. Nitroglycerin can be used because it increases venous capacity more than does sodium nitroprusside.

In patients without evidence of left ventricular decompensation or myocardial ischemia during supraceliac aortic cross-clamping, a proximal aortic mean arterial pressure of up to 120 mm Hg is acceptable. The surgeon may request lower proximal arterial pressure if friable aortic tissue is encountered. Blood flow below the aortic clamp depends on pressure and decreases further during therapy with vasodilators. In this setting, vital organs and tissues distal to the clamp are exposed to reduced perfusion pressure and blood flow. Though infrequent, maintenance of adequate cardiac output may require active intervention with inotropic drugs.

BOX 56.3 Physiologic Changes With Aortic Unclamping* and Therapeutic Intervention

Hemodynamic Changes

↓ Myocardial contractility
↓ Arterial blood pressure
↑ Pulmonary artery pressure
↓ Central venous pressure
↓ Venous return
↓ Cardiac output

Metabolic Changes

↑ Total body oxygen consumption
↑ Lactate
↓ Mixed venous oxygen saturation
↑ Prostaglandins
↑ Activated complement
↑ Myocardial-depressant factor(s)
↓ Temperature
Metabolic acidosis

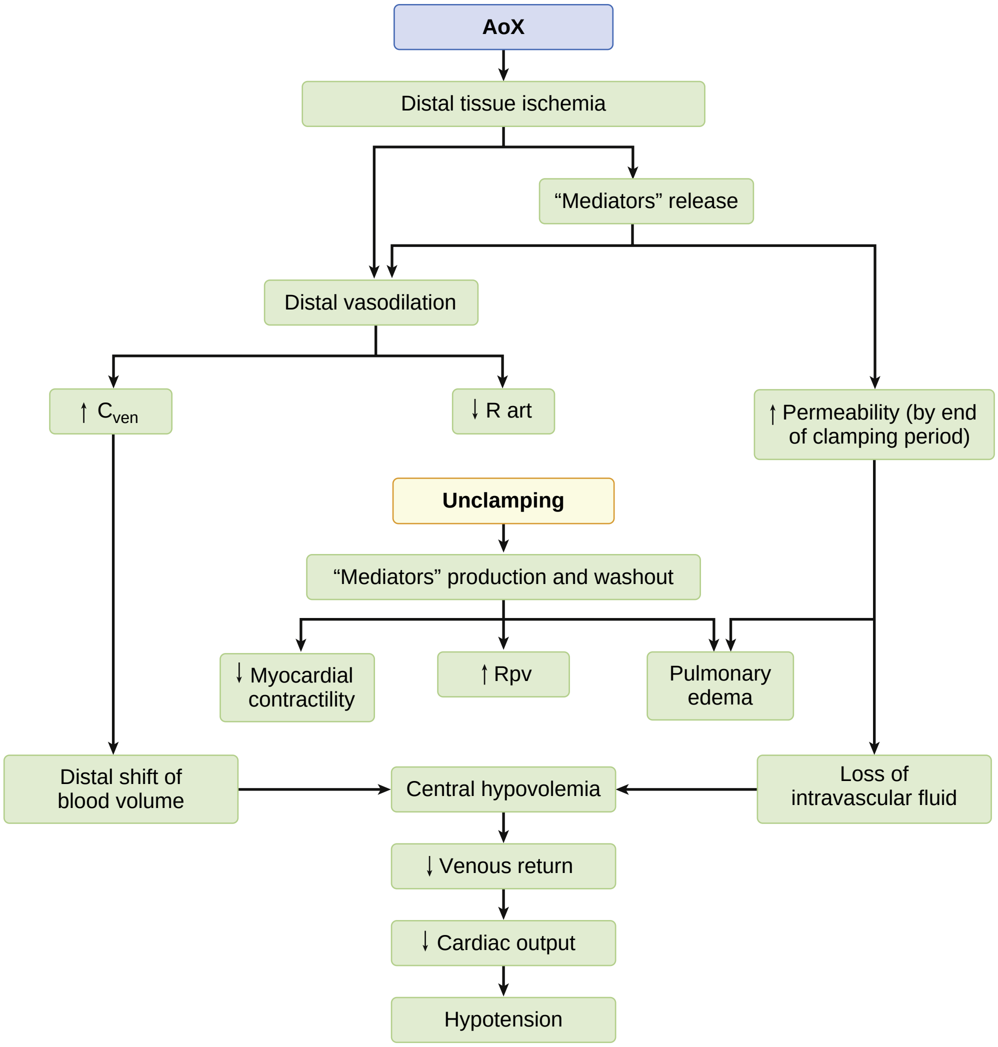
Therapeutic Interventions

↓ Inhaled anesthetics
↓ Vasodilators
↑ Fluid administration
↑ Vasoconstrictor drugs
Reapply cross-clamp for severe hypotension
Consider mannitol
Consider sodium bicarbonate

*These changes are of greater significance with longer duration of cross-clamping and with more proximal cross-clamping.

AORTIC UNCLAMPING

The hemodynamic and metabolic effects of aortic unclamping are listed in Box 56.3. The hemodynamic response to unclamping depends on many factors, including the level of aortic occlusion, total occlusion time, use of diverting support, and intravascular volume. Hypotension, the most consistent hemodynamic response to aortic unclamping, can be profound, particularly after removal of a supraceliac cross-clamp (Fig. 56.4). Reactive hyperemia in tissues and organs distal to the clamp and the resultant relative central hypovolemia are the dominant mechanisms of the hypotension. Washout of vasoactive and cardiodepressant mediators from ischemic tissues, as well as humoral factors,



AoX
Distal tissue ischemia
"Mediators" release
Distal vasodilation
↑ C_{ven}
↓ R art
↑ Permeability (by end of clamping period)
Unclamping
"Mediators" production and washout
↓ Myocardial contractility
↑ Rpv
Pulmonary edema
Distal shift of blood volume
Central hypovolemia
Loss of intravascular fluid
↓ Venous return
↓ Cardiac output
Hypotension

may also contribute to the hemodynamic responses after unclamping the aorta. These humoral factors and mediators, which may also play a role in organ dysfunction after aortic occlusion, include lactic acid, renin-angiotensin, O2 free radicals, prostaglandins, neutrophils, activated complement, cytokines, and myocardial-depressant factors.[54]

Avoidance of significant hypotension with unclamping requires close communication with the surgical team, awareness of the technical aspect of the surgical procedure, and appropriate administration of fluids and vasoactive drugs. It is essential that correction of preoperative fluid deficits, maintenance of intraoperative fluid requirements, and replacement of blood loss be accomplished before unclamping. Vasodilators, if used, should be gradually reduced and discontinued before unclamping. The inspired concentrations of volatile anesthetics should be decreased. Moderate augmenting of intravascular volume by administration of fluids (~500 mL) during the immediate prerelease period is indicated for infrarenal unclamping. More aggressive intravascular fluid administration is required in the period immediately preceding supraceliac unclamping. Maintaining increased central venous or pulmonary capillary wedge pressure during the cross-clamp period is not indicated and may result in significant overtransfusion of fluids and blood products. If significant hypotension results, gradual release of the aortic clamp and reapplication or digital compression are important measures in maintaining hemodynamic stability during unclamping. Although vasopressor requirements are minimal after release of the infrarenal clamp, significant support is often needed after the removal of supraceliac clamps. Caution must be observed when vasopressor support is used in this setting because profound proximal hypertension may occur if reapplication of the cross-clamp is required above the celiac axis. In addition, hypertension should be avoided to prevent damage to or bleeding from the vascular anastomoses.

ANESTHETIC MANAGEMENT

Intraoperative Monitoring

The potential for significant and rapid blood loss cannot be underestimated. A central line and two peripheral lines are usually used as intravenous (IV) access. The choice of the type and the size of the central line can be decided on a case-by-case basis. Placement of an arterial catheter should be routine in all patients undergoing aortic reconstruction.

As with other vascular procedures, the radial artery is most commonly selected for cannulation because of its superficial location, easy accessibility, and low complication rate. A noninvasive blood pressure cuff should be placed on the arm contralateral to the arterial catheter in the event of catheter malfunction.

A central venous catheter should be used for all open aortic procedures. It allows monitoring of CVP and administration of drugs directly into the central circulation. The routine, nonselective use of pulmonary artery catheter monitoring is not recommended. It should be reserved for patients with severely limited cardiopulmonary function or complex aortic reconstruction. In patients with good left ventricular and pulmonary function, CVP correlates well with left ventricular filling pressure. The invasive monitoring catheters can be placed before or after induction of general anesthesia. The advantage of preinduction catheter placement is assessment of the patient's awake (i.e., baseline) cardiovascular status, which allows correction of significant abnormalities in cardiac filling and function before induction.

With selective use, accurate interpretation of data, and rational treatment strategies, pulmonary artery catheter monitoring may be beneficial in high-risk patients undergoing complex aortic reconstruction. Yet the clinical value of pulmonary artery catheter monitoring in high-risk patients has not been established.[65] Clinical studies over the last 2 decades have yielded quite conflicting and variable results, including both increases and decreases in mortality. The National Heart, Lung and Blood Institute and the Food and Drug Administration (FDA)[66] sponsored a large prospective, randomized trial that compared goal-directed therapy guided by a pulmonary artery catheter with standard care without the use of a pulmonary artery catheter in high-risk surgical patients. The result found no benefit in treatment guided by a pulmonary artery catheter.[67] Yet this study did not find an increase in mortality with insertion and use of a pulmonary artery catheter.

Transesophageal echocardiography (TEE) has been used intraoperatively to assess global ventricular function, guide intravascular fluid therapy, and monitor for myocardial ischemia. Patients requiring supraceliac aortic cross-clamping have significant increases in the end-diastolic area and significant decreases in ejection fraction on echocardiography that are not completely normalized with vasodilators and frequently are not detected by pulmonary artery catheter monitoring.[56]

The optimal intraoperative monitoring techniques for patients undergoing abdominal aortic reconstruction have not been established. Existing clinical studies offer insufficient data to conclusively answer the question of whether pulmonary artery catheter or TEE monitoring improves outcome. The clinical usefulness of any monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.

Cell Salvage

Intraoperative cell salvage is a widely used technique combined with allogenic blood transfusion and in some centers is considered routine. The equipment is expensive and requires significant training and expertise. An early, nonrandomized study reported a 75% reduction in the number of allogeneic red blood cell (RBC) units transfused during elective aortic surgery with the use of cell salvage. Later randomized studies have reported conflicting results. The routine use of cell salvage during aortic surgery may not be cost-effective and thus it may best be reserved for a select group of patients with an expected large blood loss. A cost-effective option is to use the cell salvage reservoir for blood collection and activate the full salvage process only if large blood loss occurs.

Anesthetic Drugs and Techniques

Various anesthetic techniques, including general anesthesia, regional (epidural) anesthesia, and combined techniques, have been used successfully for abdominal aortic reconstruction. Combined techniques most commonly use a lumbar or low thoracic epidural catheter in addition to general anesthetic. Local anesthetics, opioids, or, more commonly, a combination of the two may be administered by bolus or continuous epidural infusion. Maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome than is the choice of anesthetic drug or technique.[14] Therefore, the specific anesthetic technique for patients undergoing abdominal aortic reconstruction is important insofar as it allows rapid and precise control of hemodynamic parameters. Given the frequent incidence of cardiac morbidity and mortality in patients undergoing aortic reconstruction, factors that influence ventricular work and myocardial perfusion are of prime importance. Induction of general anesthesia should ensure that stable hemodynamics are maintained during loss of consciousness, laryngoscopy and endotracheal intubation, and the immediate postinduction period. A variety of IV anesthetics (propofol, etomidate, thiopental) are suitable. The addition of a short-acting, potent opioid such as fentanyl or sufentanil usually provides stable hemodynamics during and after induction of anesthesia. Volatile anesthetics may be administered in low concentrations before endotracheal intubation during assisted ventilation as an adjunct to blunt the hyperdynamic response to laryngoscopy and endotracheal intubation. Esmolol 10 to 25 mg, sodium nitroprusside 5 to 25 μg, nitroglycerin 50 to 100 μg, or clevidipine 100 mcg and phenylephrine 50 to 100 μg should be available for bolus administration during induction if needed to maintain appropriate hemodynamics.

Maintenance of anesthesia may be accomplished with a combination of a potent opioid (fentanyl or sufentanil) and an inhaled anesthetic (sevoflurane, desflurane, or isoflurane) (i.e., balanced anesthesia). Patients with severe left ventricular dysfunction may benefit from a pure opioid technique, but a balanced anesthetic technique allows the clinician to take advantage of the most desirable characteristics of potent opioids and inhaled volatile anesthetics while minimizing their undesirable side effects. Nitrous oxide can be used to supplement either an opioid or an inhaled anesthetic.

Various regional anesthetic and analgesic techniques have been used effectively during and after aortic reconstruction. For over 2 decades, interest has focused on the use of regional anesthetic and analgesic techniques to reduce the incidence of perioperative morbidity in patients undergoing aortic reconstruction. The benefits of combined general and epidural anesthesia intraoperatively, with or without epidural analgesia continued into the postoperative period, remain controversial.[13,14,68-71] Moreover, studies that have reported improved outcome do not determine whether the benefit results from the intraoperative anesthetic technique or the postoperative analgesic regimen (or a combination of the two). In a randomized trial using epidural morphine in patients undergoing aortic surgery, Breslow and associates[72] found attenuation of the adrenergic response and a less frequent incidence of hypertension in the postoperative period. A large randomized trial reported no reduction in nonsurgical complications with the use of intrathecal opioid.[15] The effects of the anesthetic or analgesic technique on the incidence of perioperative myocardial ischemia have received considerable attention. Four randomized trials, with nearly 450 combined patients undergoing aortic reconstruction, failed to demonstrate a reduction in the incidence of perioperative,[14,73] intraoperative,[74] or postoperative[70] myocardial ischemia when epidural techniques were used. Additionally, randomized trials have not demonstrated a reduction in the incidence of cardiovascular, pulmonary, or renal complications after aortic surgery with the use of epidural techniques.[13,14,69,70,75]

The duration and intensity of postoperative care after aortic surgery are critically dependent on the physiologic derangements incurred during the perioperative period (i.e., depression of consciousness, hypothermia, excessive intravascular fluids, incisional pain, ileus, and respiratory depression), as well as on the development of certain less common, but more severe postoperative complications (i.e., MI, pneumonia, sepsis, renal failure, and decreased tissue perfusion). Length of hospital stay may therefore be considered the outcome variable most directly proportional to an integrated final negative effect of all significant perioperative morbidity (excluding in-hospital death) and the variable most likely to be altered by the anesthetic or analgesic technique. Randomized trials have not demonstrated any reduction in length of hospital stay after aortic surgery with the use of regional techniques. Norris and colleagues[14] reported the results of a randomized clinical trial comparing alternative combinations of intraoperative anesthesia (i.e., general or combined epidural and general) and postoperative analgesia (i.e., IV patient-controlled analgesia [PCA] or epidural PCA) with respect to length of stay after abdominal aortic surgery. Two unique features of the trial included a factorial design (Fig. 56.5), which allowed the inclusion of all four combinations of intraoperative anesthesia and postoperative analgesia and the ability to separate the influence of time period and technique, and a double-blind design, which helped eliminate investigator and treating physician bias. The study rigorously protocolized perioperative management, standardized postoperative surgical care, and optimized postoperative pain management. Although the overall length of stay was much shorter (median, 7.0 days) than that reported in other studies,[13,68,70,75] they were not able to demonstrate a reduction in length of stay or direct medical costs based on anesthetic or analgesic technique (Table 56.6). The overall incidence of postoperative complications in the trial was low and not different based on anesthetic or analgesic technique. Postoperative pain was well controlled overall, with similar pain scores in both analgesic treatment groups. Thus, if perioperative care and pain relief are optimized, epidural anesthetic and analgesic techniques for aortic surgery offer no major advantage or disadvantage over general anesthesia and IV PCA.

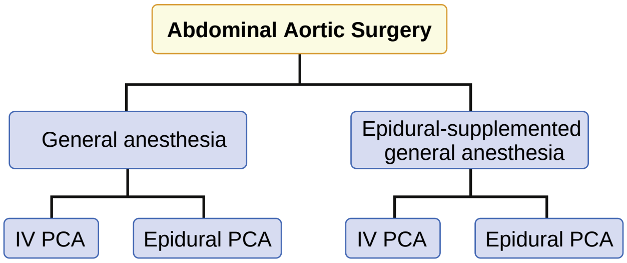

Fig. 56.5 Outline of factorial study design. This design allows the inclusion of all four possible combinations on intraoperative anesthesia and postoperative analgesia and the ability to separate the influences of time period and technique. Data analysis by treatment group, intraoperative treatment, postoperative treatment, and any epidural activation, as well as simultaneous consideration of both intraoperative and postoperative treatments in the same model (factorial analysis), is possible and allows improvement in outcome to be attributed to the intraoperative anesthesia, postoperative analgesia, the combination of the two, or to unrelated factors. *IV*, Intravenous; *PCA*, patient-controlled analgesia.

The use of epidural local anesthetics in combination with general anesthesia during aortic reconstruction poses several problems, including hypotension at the time of aortic unclamping and the need for increased intravascular fluid and vasopressor requirements. Supraceliac aortic cross-clamping may significantly exaggerate these disadvantages, and, as a result, some clinicians avoid running local anesthetics in the epidural around the period of aortic clamping and unclamping. Epidural opioids without local anesthetics can be used in the interim and local anesthetic can be given later, after aortic unclamping, when hemodynamics and intravascular volume have stabilized. Although elective aortic reconstruction via the retroperitoneal approach using straight epidural anesthesia (no general anesthetic) has been reported, this technique is not recommended for routine use.

Hypertension and tachycardia are aggressively controlled during emergence by the use of short-acting drugs such as esmolol, nitroglycerin, clevidipine, or sodium nitroprusside. Emergence from anesthesia should be conducted after restoration of circulation and establishment of adequate organ perfusion. Hemodynamic, metabolic, and temperature homeostasis must be achieved before extubation; otherwise, patients should be transported intubated to the intensive care unit (ICU).

Temperature Control

Postoperative hypothermia is associated with many undesirable physiologic effects and may contribute to adverse outcomes (see also Chapter 80). Normothermia should be maintained before skin incision by increasing ambient temperature in the operating room, applying warm cotton blankets, and warming IV fluids. If significant hypothermia occurs early in the procedure, normothermia is extremely difficult to achieve, and emergence and tracheal extubation may be delayed. During surgery, all fluids and blood products should be warmed before administration. A forced-air warming blanket should be applied over the upper part of the body. The lower part of the body should not be warmed

TABLE 56.6 Duration of Hospital Stay and Direct Medical Costs by Randomized Treatment Assignment for Patients Surviving to Discharge after Abdominal Aortic Surgery

during the cross-clamp period because doing so can increase injury to ischemic tissue distal to the cross-clamp by increasing metabolic demands.

THORACOABDOMINAL AORTIC SURGERY

Open repair of the thoracoabdominal aorta is widely regarded as the most challenging surgical procedure in terms of overall anesthetic and perioperative management. Surgical repair is required for a spectrum of disease, including degenerative aneurysm, acute and chronic dissection, intramural hematoma, mycotic aneurysm, pseudoaneurysm, penetrating aortic ulcer, coarctation, and traumatic aortic tear. Since the first thoracoabdominal aortic aneurysm (TAA) repair in 1955, tremendous advances have been made in the field. These advances have led to significant reductions in operative mortality and perioperative complications. However, even in centers where numerous procedures are performed, morbidity and mortality are frequent, especially in patients with dissecting or ruptured aneurysms. To successfully care for these patients, the anesthesiologist must be knowledgeable in the areas of one-lung ventilation; extracorporeal circulatory support, including circulatory arrest; renal and spinal cord protection; induced hypothermia; invasive hemodynamic monitoring, including TEE; massive transfusion; and management of coagulopathy. Intraoperative management requires a team effort with intimate cooperation among surgeons, anesthesiologists, perfusionists, nurses, and electrophysiologic monitoring staff. Endovascular stent-graft repair of lesions that affect the descending thoracic and thoracoabdominal aorta is evolving rapidly. As discussed later, accumulating experience with stent-graft repair of thoracic aortic aneurysm, dissection, and traumatic tear has demonstrated this modality to be an effective alternative to open repair for select patients.

ETIOLOGY AND CLASSIFICATION

Aneurysms of the thoracoabdominal aorta occur primarily because of atherosclerotic degenerative disease (80%) and chronic aortic dissection (17%).[76] The remainder are caused by either trauma or connective tissue diseases involving the aortic wall from conditions such as Marfan syndrome, cystic medial degeneration, Takayasu arteritis, or syphilitic aortitis. The true incidence of TAA is unknown, but population studies suggest a prevalence much less than that of infrarenal AAA. Degenerative and dissecting TAAs differ in their associated risk factors, extent of aortic involvement, and natural history. Thus complete characterization of each TAA is required to formulate a comprehensive treatment plan. Development of both degenerative and dissecting TAAs is ultimately related to weakening of the aortic wall. Although the natural history of TAA without surgery is uncertain, enlargement tends to be progressive and nonoperative management is generally associated with a poor prognosis. With progressive enlargement, nutritional blood flow to the aorta is compromised. The increasing diameter is associated with increased wall tension, even when arterial pressure is constant (law of Laplace). The frequent incidence of associated systemic hypertension enhances aneurysm enlargement.

Degenerative and dissecting TAAs are symptomatic at initial evaluation in 57% and 85% of patients, respectively. The most common initial complaint is back pain. Additional symptoms can be caused by compression of organs or structures adjacent to the aneurysm. Aortic rupture, as a manifestation of TAA, occurs with equal frequency (9%) in both degenerative and dissecting aneurysms. Rupture of the thoracic and abdominal segments occurs with equal frequency and primarily in patients with aneurysms larger than 5 cm. Surgical repair is usually recommended when aneurysm diameter exceeds 6 cm, but earlier repair may be offered to patients with Marfan syndrome and those with a strong family history of an aortic aneurysm.

In addition to cause, aneurysms of the thoracoabdominal aorta may be classified according to their anatomic location. In 1986, Crawford and colleagues,[76] recognizing the correlation between aneurysm extent and clinical outcome, proposed a classification based on the extent of aortic involvement (Fig. 56.6). The Crawford classification defines aneurysms as types I, II, III, and IV and is appropriately applied to aneurysms of all causes (degenerative and dissecting). Type I aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta. Type II aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta. Type III aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta. Type IV aneurysms involve all or most of the abdominal aorta, including the visceral segment. Types II and III are the most difficult to repair because they involve

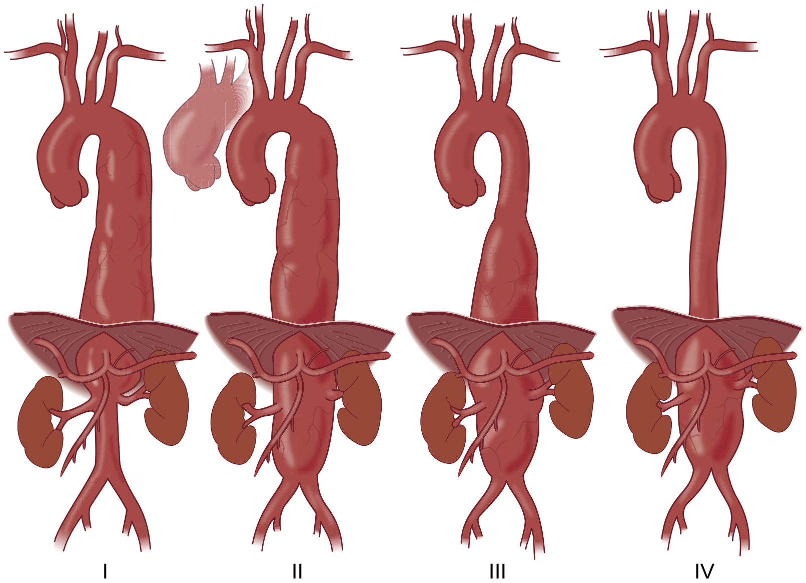

Fig. 56.6 The Crawford classification of thoracoabdominal aortic aneurysms is defined by anatomic location and the extent of involvement. *Type I* aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta; *type II* aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta; *type III* aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta; and *type IV* aneurysms involve all or most of the abdominal aorta, including the visceral segment.

both the thoracic and the abdominal segments of the aorta. Patients with Crawford type II aneurysms are at greatest risk for paraplegia and renal failure from spinal cord and kidney ischemia during cross-clamping. Even with extracorporeal circulatory support, an obligatory period occurs when blood flow to these organs is interrupted because the origin of the blood flow is between the cross-clamps. For this reason, protective measures to prevent ischemic injury are important in reducing morbidity.

Aortic dissection, with or without aneurysm formation, has likewise been classified according to the extent of aortic involvement. The most widely used classification, proposed by DeBakey and colleagues, defines aortic dissection as types I, II, and III (Fig. 56.7).

Type I aneurysms begin in the ascending aorta and extend throughout the entire aorta. These lesions are usually repaired via a two-stage approach, with the first procedure on the ascending aorta and aortic arch and the second procedure on the descending thoracic aorta. Type II aneurysms are confined to the ascending aorta. Both types I and II often involve the aortic valve and cause aortic regurgitation, and sometimes they involve the ostia of the coronary arteries. Type III aneurysms begin just distal to the left subclavian artery (SCA) and extend either to the diaphragm (type IIIA) or to the aortoiliac bifurcation (type IIIB).

Another commonly used classification of aortic dissection is the Stanford classification. This more simplified classification divides aortic dissection into those that involve the ascending aorta (Stanford type A) and those that do not involve the ascending aorta (Stanford type B). Aortic dissection is also classified by duration, with those less than 2 weeks classified as acute and those greater than 2 weeks classified as chronic. This classification has very significant mortality implications, with much higher mortality in the acute phase.

Acute aortic dissection involving the ascending aorta (DeBakey types I and II, Stanford type A) is a surgical emergency that requires immediate cardiac surgical repair (see also Chapter 54). Acute dissections involving the descending aorta (DeBakey type III, Stanford type B) are most often treated conservatively (i.e., arterial blood pressure, heart rate, and pain control) because surgical repair has no proved benefit over medical or interventional treatment in stable patients. Early surgical intervention may be required for a variety of reasons, including aneurysmal formation, impending rupture, organ or leg ischemia, and inadequate response to medical therapy. In approximately 20% to 40% of patients with chronic aortic dissection, significant aneurysmal dilatation of the descending thoracic or thoracoabdominal aorta will develop.

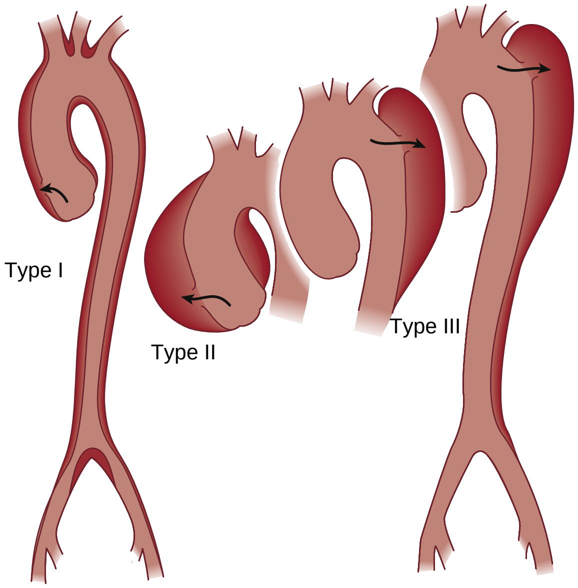

Fig. 56.7 The DeBakey classification of dissecting aneurysms of the aorta. *Type I* has an intimal tear in the ascending aorta with dissection extending down the entire aorta. *Type II* has an intimal tear in the ascending aorta with dissection limited to the ascending aorta. *Type III* has an intimal tear in the proximal descending thoracic aorta with dissection either limited to the thoracic aorta (type IIIA) or extending distally to the abdominal aorta or aortoiliac bifurcation (type IIIB).

MORBIDITY AND MORTALITY

Despite tremendous development in surgical and anesthetic technique, mortality and complication rates remain frequent for open surgical repair of TAA. Patients who undergo replacement of the entire thoracoabdominal aorta (Crawford extent type II) have the most frequent perioperative risk. Contemporary mortality rates reported from large institutions range from 5% to 14%. Statewide and nationwide mortality rates may be considerably more frequent (~20%). The perioperative mortality rate may significantly underestimate the risk associated with TAA repair. In a large statewide series, the mortality with elective TAA repair was 19% at 30 days and 31% at 365 days.[77]

The incidence of paraplegia or paraparesis in patients undergoing surgical repair of TAA is reported to be 3.8% to 40%, depending on complex factors such as anatomic location, the duration of cross-clamping, the use of protective measures, the degree of dissection, and whether the aneurysm has ruptured. Extensive dissecting TAA repair carries the highest risk for neurologic deficit. A contemporary report of 210 consecutive open TAA repairs reported three patients with paraplegia and two with temporary paraparesis for an overall rate of neurologic deficit of 2.4% (1.4% permanent).[78] Renal failure occurs in 3% to 30% of patients, depending on similar factors noted earlier. Overall, approximately 6% of patients need postoperative dialysis after TAA repair, which is associated with high mortality (30% to 60%). Gastrointestinal complications occur in approximately 7% of patients and are associated with a mortality approaching 40%. Not surprisingly, pulmonary complications are the most common problem associated with TAA repair. The incidence of postoperative pulmonary insufficiency approaches 50%, with 8% to 14% of patients requiring tracheostomy. As with all other vascular surgical procedures, cardiac complications are common and a leading cause of perioperative mortality. In general, perioperative mortality and major complication rates after open isolated descending thoracic aortic replacement are lower than those described for TAA repair.

PREOPERATIVE PREPARATION AND MONITORING

Open surgical TAA repair requires extensive preoperative evaluation and planning. The evaluation and management of coexisting cardiac and pulmonary disease are discussed earlier. Before the day of surgery, the anesthesiologist and vascular surgeon should discuss, at a minimum, extent of the aneurysm and technique of surgical repair, plans for distal aortic perfusion, monitoring for spinal cord ischemia (SCI), renal and spinal cord protection, hemodynamic monitoring, and ventilation strategy. Depending on the extent and the location of the aortic disease in the descending aorta, the decision to use left heart bypass or not is usually made.

Blood loss during TAA repair can be profound, and the need for massive transfusion must not be underestimated. This author routinely has 10 units of packed RBCs, 10 units of thawed fresh frozen plasma, and several units of platelets immediately available in the operating room, and additional units must be readily obtainable.

Large-bore IV access is obviously important, especially if partial bypass (in contrast to full bypass) is planned, because it is difficult or impossible for the perfusionist to administer fluid or blood products into the closed partial bypass circuit. Large-sized central venous catheters with introducer sheaths for pulmonary artery catheters and large bore peripheral IVs are recommended. Rapid infuser systems are used to allow the delivery of up to 1500 mL/min of blood products at a temperature of 37°C to 38°C. A right radial arterial catheter is used for aneurysms involving the proximal descending thoracic aorta because occasionally the cross-clamp is placed proximal to the left subclavian artery, thus occluding flow to the left upper extremity. When distal aortic perfusion techniques are used, arterial blood pressure distal to the cross-clamps can be monitored . This can be accomplished with the placement of a right femoral arterial catheter, or the surgical team can place a catheter directly into the femoral artery or distal aorta. This catheter monitors perfusion pressure to the kidneys, spinal cord, and mesenteric circulation during the time when the cross-clamps are high on the descending aorta and the lower body region is perfused by a shunt or bypass circuit. Radial and femoral arterial pressure should be simultaneously displayed on the anesthesiologist's monitor and a monitor visible to the surgeons and the perfusionists. TEE is used routinely during TAA repair (see also Chapter 37). When TEE is used by a properly trained individual, assessment of left ventricular end-diastolic volume, myocardial ischemia, and valvular function is possible. It is also possible to determine the size and extent of the aneurysm.

A double-lumen endobronchial tube or a bronchial blocker should be inserted for the purpose of one-lung ventilation (see also Chapter 53). One-lung ventilation provides optimal visualization of the surgical field and reduces retraction-related trauma to the left lung. The double-lumen tube is usually changed, if possible, to a single-lumen tube at the completion of surgery. This facilitates ICU management of pulmonary hygiene and reduces resistance to breathing during weaning in the postoperative period. Many centers use electrophysiologic monitoring with somatosensory evoked potentials (SSEPs) or motor evoked potentials (MEPs) to monitor for SCI (see also Chapter 39). These monitoring techniques may be helpful in both identifying the important intercostal arteries that perfuse the spinal cord and confirming successful reimplantation into the aortic graft. If SCI is identified, cross-clamps can often be repositioned, upper or lower body blood pressure can be increased to augment perfusion through collateral channels, or other measures may be taken to protect the spinal cord (i.e., cerebrospinal fluid [CSF] drainage, induced hypothermia, or intrathecal pharmacologic agents). These techniques are discussed later. Three general problems exist with SSEP monitoring when used during TAA repair. First, sensory monitoring is more likely to detect lateral and posterior sensory column ischemia and is a poor monitor for the anterior motor column. As a result, paraplegia can occur despite normal SSEP signals. Second, inhaled anesthetics and hypothermia can significantly interfere with SSEP signals. Third, ischemia affects peripheral nerves, and ischemia in the lower extremities delays conduction from the usual stimulation sites (e.g., posterior tibial nerve). To eliminate the peripheral nerves as a confounding factor, spinal stimulation via a lumbar epidural electrode can be used, which may be more specific for ischemic injury than peripheral monitoring alone. Lower extremity and peripheral nerve ischemia can be avoided with the use of distal aortic perfusion techniques. To avoid lower extremity ischemia from occlusion of the left femoral artery at the insertion site of the retrograde perfusion cannula, some surgeons suture a small-caliber graft onto the femoral artery (end to side) for insertion of the cannula, which allows both antegrade and retrograde perfusion. These limitations of SSEP monitoring probably account for the lack of identification of critical spinal arteries. The transcranial MEP technique has been used successfully to monitor the anterior columns of the spinal cord. The technique is relatively simple and can be viewed as a "train-of-four" for the brain and spinal cord. Electrical stimulation over the motor cortex activates α-motor neurons, and evoked electromyographic responses are obtained in lower extremity muscle. Only electromyogenic responses are specific for the status of the motor neurons in the anterior horn gray matter. Bilateral recording needles should be placed in the popliteal fossae (i.e., popliteal nerve) and bilateral surface electrodes over the gastrocnemius and tibialis anterior muscles. Bilateral stimulating needles are routinely placed in the popliteal fossae to monitor direct muscle responses and the level of neuromuscular blockade. During aortic cross-clamping, MEPs are monitored every minute. A reduction in MEP amplitude to less than 25% of baseline is considered an indication of SCI and requires corrective measures. Because signal averaging is not required and the anterior horn cells react with an almost immediate functional loss after the onset of ischemia, the technique can be used to rapidly identify intercostal arteries supplying the spinal cord. Additionally, the technique can be used to evaluate the adequacy of distal aortic perfusion and the patency of reimplanted critical intercostal arteries. Careful titration of a short-acting neuromuscular blocker is required to maintain a stable level of neuromuscular blockade. Complete neuromuscular blockade makes MEP monitoring impossible. Isoflurane, desflurane, sevoflurane, and N2O depress synaptic conduction and significantly decrease the amplitude of myogenic MEPs. Although modifications of the stimulating technique have somewhat improved monitoring with inhaled anesthetics, a total IV anesthetic technique may be optimal. Fentanyl and ketamine have little effect on myogeneic MEPs and have been used successfully as a combined anesthetic in a large series of patients undergoing TAA repair with MEP monitoring.[78] This series of 210 consecutive patients had the lowest rate of neurologic deficit (2.4%) and permanent paraplegia (1.4%) reported.[78] Body temperature should be monitored at two sites (core and peripheral) to assess cooling and warming when bypass techniques are used. However, an important difference exists between full and partial bypass in temperature monitoring. With full bypass, perfusion is usually into the ascending aorta, and typically the upper body core temperature (i.e., nasopharynx or esophagus) cools and warms fastest, whereas the lower body temperature changes more slowly. With partial bypass, the opposite is true. The blood from bypass is returned into the femoral artery, and the lower part of the body (i.e., rectum or bladder) changes before the upper part changes. This difference is important to recognize to achieve complete cooling and warming because the lagging temperature should be the end point for cooling and warming.

ANESTHETIC MANAGEMENT

Simple Aortic Cross Clamping

Descending thoracic and thoracoabdominal aortic surgery can be performed without extracorporeal support (i.e., left heart bypass or cardiopulmonary bypass). The "clamp-and-sew" technique has had relatively favorable outcomes, but these cases are from institutions with extensive clinical experience and the shortest cross-clamp times. Advocates of this technique favor its surgical simplicity. However, the benefits of avoiding the complexity and complications of bypass must be weighed against the risk for vital organ ischemia and complications such as renal failure and paraplegia. Other than the location and extent of the aneurysm, the duration of cross-clamping on the aorta is the single most important determinant of paraplegia and renal failure with the clamp-and-sew technique. With longer clamp times, specific adjuncts directed against end-organ ischemic complications have been described in literature. Such adjuncts include epidural cooling for spinal cord protection, regional hypothermia for renal protection, and in-line mesenteric shunting to reduce visceral ischemia, although they lack enough clinical evidence to support any of them.

When the simple clamp-and-sew technique is used, the application of the aortic cross-clamp results in significant proximal hypertension, which requires active pharmacologic intervention. Management strategies have been discussed previously in the section on abdominal aortic reconstruction.

Left Heart Bypass

Maintaining lower body perfusion with the use of retrograde distal aortic perfusion reduces ischemic injury and improves outcome, provided the pressure is high enough to perfuse the organs. The simplest method of providing distal aortic perfusion is a passive conduit or shunt. The heparin-bonded Gott shunt was developed to avoid the need for systemic heparinization and is used to divert flow passively from the left ventricle or proximal descending thoracic aorta to the distal aorta. Some centers place a temporary axillary-to-femoral artery graft to function as a shunt during aortic cross-clamping. Partial bypass, also referred to as left heart bypass or left atrial-to-femoral bypass, is the most commonly used distal aortic perfusion technique (Fig. 56.8). This technique allows adjustment of blood flow and usually draws blood from the left atrium and returns blood to the left femoral artery. A centrifugal pump is used (Biomedicus, Eden Prairie, MN), and full-dose systemic heparin is not needed because the circuit is coated with heparin. The typical heparin dose for partial bypass is 100 units/kg. With this technique, an oxygenator is unnecessary because only the left side of the heart is bypassed. Insertion of a heat exchanger into the circuit allows cooling and warming, which is beneficial but not essential. Variations of left heart bypass include cannulating the aortic arch or proximal descending thoracic aorta instead of the left atrium. With this circuit, the left ventricle is relieved of the increased afterload during

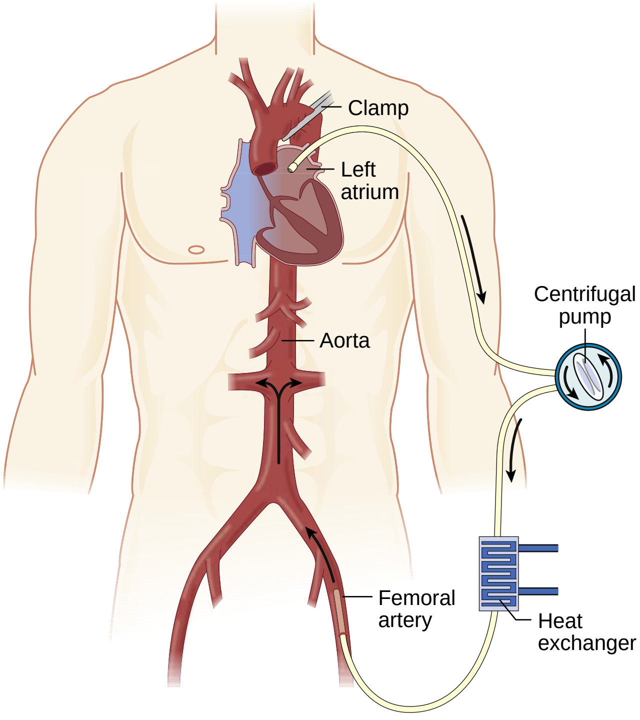

Fig. 56.8 Diagram of left atrial-femoral bypass. The left atrium and the left femoral artery are cannulated, and a centrifugal pump is used with heparin-coated tubing. A heat exchanger may be added into the circuit for cooling and rewarming.

aortic cross-clamping. With left atrial cannulation, the left ventricle is relieved of preload and cardiac output is reduced. Either way, proximal hypertension is controlled, the work of the ventricle is decreased, and perfusion is provided to the distal aorta. When hypothermia (30°C) is combined with atrial cannulation, approximately 15% of patients experience new atrial fibrillation. Although most patients revert to sinus rhythm on rewarming, direct cardioversion may be required.

During left heart bypass, it is essential that arterial blood pressure be monitored above and below the aortic cross-clamps. Careful control of intravascular volume, bypass pump flow, and vasoactive drugs is required to achieve the target blood pressures. Management of left heart bypass requires continuous communication and cooperation between the surgeon, anesthesiologist, and perfusionist. We typically set the initial pump flow to approximately 50% of the patient's cardiac output with application of the proximal aortic clamp. Flow is then adjusted to maintain target proximal and distal pressures. Administration of vasodilators is very infrequently required at this stage. With no vital organ ischemia, the surgeon can complete the proximal anastomoses in an unhurried fashion. With sequential aortic clamping, intercostal arteries can be reimplanted with minimal adjustments of pump flow. Pump flow is eventually reduced significantly during reimplantation of the visceral and renal arteries. At this point, distal perfusion is only to the lower extremities. Moderate hypothermia (32°C) during bypass is used to protect the vital organs during obligate periods of ischemia. After completion of the distal anastomoses, pump flow is increased, and the patient is actively warmed to 37°C.

Deep Hypothermic Circulatory Arrest

Complex aneurysms involving the aortic arch often require elective cardiopulmonary bypass with an interval of deep hypothermic (15°C) circulatory arrest (DHCA) because cerebral blood flow is transiently interrupted during surgery (see also Chapter 54). Bypass can be accomplished by cannulation of the femoral artery and the femoral vein (i.e., femoral-femoral bypass). During the interval of DHCA, some centers also use anterograde (i.e., innominate artery) or retrograde (i.e., internal jugular vein) selective cerebral perfusion with cold oxygenated blood to extend the safe maximum duration of circulatory arrest. Without this technique, 45 to 60 minutes is thought to be the safe limit of DHCA, but 90 minutes has been reported with selective cerebral perfusion. DHCA also may be necessary whenever the location, extent, or severity of aortic disease precludes placement of a proximal aortic clamp during thoracic or thoracoabdominal aortic repair. This is often the case in patients with previous aortic arch repair, in which adhesions and scarring make application of the proximal aortic cross-clamp difficult or impossible during TAA repair. DHCA eliminates the need for proximal aortic clamping and allows a bloodless field for the proximal aortic anastomosis. Some centers advocate the routine use of DHCA during complex aortic reconstruction because deep hypothermia may provide better end-organ and spinal cord function. This potential benefit must be carefully weighed against the risks associated with prolonged cardiopulmonary bypass and circulatory arrest. After completion of the proximal anastomosis and intercostal artery-to-graft anastomoses under DHCA, the aortic graft is cannulated and bypass flow is reestablished to the upper part of the body. During a period of hypothermic low bypass flow, the distal anastomoses are completed and then rewarming is initiated.

Anesthetic Technique

No single anesthetic technique is best for TAA repair. Usually, balanced anesthesia is provided with a combination of an opioid, a low-dose potent volatile anesthetic, a benzodiazepine, and a muscle relaxant. A total IV technique may be optimal if transcranial MEP monitoring is used. Induction of general anesthesia should be slow and controlled. Hypertension should be avoided because acute stress on the aneurysm can cause rupture. The heart rate should be maintained at or below baseline because myocardial ischemia is often related to the heart rate. Extubation should always take place in the ICU and only after a significant period of hemodynamic and metabolic stability. The postoperative analgesic regimen should focus on pain control and stable hemodynamics.

Spinal Cord Ischemia and Protection

Paraplegia is a devastating complication of aortic surgery. The incidence of paraplegia is reported to be 0.5% to 1.5% for coarctation repair, 0% to 10% for thoracic aneurysm repair, 10% to 20% for thoracoabdominal repair, and as high as 40% for extensive dissecting TAA repair. The spinal cord receives its blood supply from two posterior arteries (≈25%) and one anterior spinal artery (≈75%) (Fig. 56.9). The posterior spinal arteries, which supply the sensory tracts in the spinal cord, receive flow from the posterior and inferior cerebellar arteries, the vertebral arteries, and

Fig. 56.9 Diagram of the blood supply to the spinal cord showing the anterior and posterior radiculomedullary branches seen in a lateral view. The primary blood supply to the thoracolumbar portion of the spinal cord is derived from the artery of Adamkiewicz; its origin varies but usually branches off the aorta in the T9 to T12 region.

the posterior radicular arteries. The anterior spinal artery, which supplies the motor tracts in the spinal cord, is formed by two branches of the intracranial portion of the vertebral arteries. The upper cervical segment of the spinal cord receives most of its blood flow from the vertebral arteries. The thoracic portion of the anterior spinal artery is supplied by the anterior radicular arteries (one or two cervical, two or three thoracic, and one or two lumbar). The largest of the radicular arteries is called the great radicular artery (GRA) or the artery of Adamkiewicz (AKA). The AKA is the major blood supply to the lower two thirds of the spinal cord. The segmental supplier of the AKA is variable (T5-L5) but is located between T9 and T12 in approximately 75% of cases. The variation in origin of the AKA explains why even infrarenal aortic aneurysm repair is associated with a 0.25% incidence of paraplegia. The specific impact of extensive segmental artery sacrifice on spinal cord perfusion during TAA repair is poorly understood.

Various methods can facilitate preventing ischemic injury to the spinal cord. Distal aortic perfusion with extracorporeal support reduces the incidence of paraplegia. Any of the various methods of distal bypass are likely to be beneficial when the anticipated cross-clamp time is longer than 30 minutes, but they are probably not beneficial when cross-clamp time is less than 20 minutes. CSF drainage is frequently used to improve spinal cord perfusion during TAA repair and is often used in combination with distal aortic perfusion. Spinal cord perfusion pressure is defined as distal mean aortic pressure minus CSF pressure or central venous pressure, whichever is greatest. Autoregulation of spinal cord blood flow is similar to cerebral autoregulation, and blood flow is relatively constant over the range of 50 to 125 mm Hg. During hypoxia or hypercapnia, autoregulation is lost, and flow becomes linearly related to perfusion pressure. Thus, significant flow may remain even at very low perfusion pressure. Drainage of CSF is important because CSF pressure often increases (by 10 to 15 mm Hg) with cross-clamping of the descending thoracic aorta. The increase in CSF pressure reduces spinal cord perfusion pressure and increases the likelihood of ischemic spinal cord injury.

Despite evidence from animal studies that CSF drainage protects the spinal cord, clinical use of this technique is controversial. One randomized trial reported a reduced incidence of paraplegia, but another reported no benefit. Most of the evidence in support of CSF drainage comes from nonrandomized historical cohort studies in which the technique is used in combination with other adjuncts, such as intrathecal papaverine and hypothermic partial bypass. Coselli and colleagues[79] offered the strongest evidence supporting the efficacy of CSF drainage. They conducted a prospective, randomized clinical trial to evaluate the impact of CSF drainage on the incidence of spinal cord injury after Crawford type I and II TAA repair. CSF drainage resulted in an 80% reduction in the relative risk for a postoperative deficit. Nine patients in the control group (13%) had paraplegia or paraparesis versus only two patients in the CSF drainage group (2.6%). Left heart bypass, moderate heparinization, permissive mild hypothermia, and reimplantation of patent intercostal and lumbar arteries were performed in both treatment groups. The target CSF pressure was 10 mm Hg. CSF drainage also reverses delayed-onset neurologic deficit after open and endovascular TAA repair.[80]

Although CSF drainage is widely used during TAA repair, it has risks. Potential complications include headache, meningitis, chronic CSF leakage, spinal or epidural hematoma, and subdural hematoma. The possibility of intraspinal pathologic processes should be considered in any patient with a postoperative lower extremity neurologic deficit. A retrospective review of 230 patients who underwent TAA repair with CSF drainage reported eight subdural hematomas (3.5%).[81] High-volume CSF drainage was identified as a risk factor for its occurrence. Six patients had subdural hematomas detected during hospitalization, with an associated mortality of 67%. Two patients were seen in a delayed fashion, and both required an epidural blood patch to control chronic CSF leakage.

Hypothermia is probably the most reliable method of neuroprotection from ischemic injury. By reducing O2 requirements by approximately 5% for each degree centigrade, a two-fold prolongation of tolerated cross-clamp time is achieved by cooling even to mild hypothermia (34°C). Because the reduction in metabolic rate is linearly related to temperature, moderate or profound hypothermia provides even greater protection. Both systemic and regional spinal cord cooling could be beneficial. Systemic hypothermia can be achieved with either full cardiopulmonary bypass (with or without DHCA) or partial bypass. Cooling to 30°C to 32°C with left atrial-to-femoral bypass in conjunction with CSF drainage was associated with no permanent neurologic sequelae in a series of 20 patients despite a relatively long average cross-clamp time (≈70 minutes).[82] Regional cooling of the spinal cord by cold perfusion of the AKA with blood or crystalloid provides significant protection during spinal ischemia in animal models. Regional cooling is beneficial in humans who received epidural infusions of 4°C saline. Even if active cooling is not used, it is advantageous to allow patients to passively cool to 33°C to 34°C during TAA repair. With passive cooling, the challenge is rewarming after the surgical repair. This is most easily accomplished with the use of a forced-air blanket over the upper part of the body. The lower body region should not be actively warmed because warming ischemic tissue increases metabolic requirements, acidosis, and ischemic injury.

Many drugs have been studied in an attempt to reduce the incidence of ischemic spinal cord injury. Barbiturates provide significant protection. Corticosteroids provide protection in dogs but were beneficial in humans only when they were combined with CSF drainage. Calcium channel blockers were not consistently shown to be protective against SCI. *N*- methyl-D-aspartate (NMDA) receptor antagonists have been investigated because ischemic injury appears to be related to increased levels of excitatory amino acids (particularly glutamate), which allow increased permeability to Ca2+ ions and high intracellular Ca2+ concentrations. Dextrorphan (a noncompetitive NMDA receptor antagonist) showed benefit during SCI in animals. Magnesium, another NMDA receptor antagonist, improves recovery from SCI in rat and dog models when administered intrathecally. Naloxone is protective in patients with traumatic spinal cord injuries and in a rabbit model of spinal ischemia. Other than the use of corticosteroids and naloxone at a few centers, most of these agents are considered investigational. Preoperative spinal cord angiography has been used in patients with TAA. The rationale for this highly invasive angiographic procedure is that precise identification of intercostal arteries giving rise to the AKA will allow focused reimplantation of these vessels during surgical repair and help prevent spinal cord injury. Selective intercostal angiography identifies the AKA when an intercostal branch is found making a cephalad hairpin turn to enter the spinal canal and supply a midline longitudinal artery (i.e., the anterior spinal artery) (Fig. 56.10). The AKA can be identified in 43% to 86% of patients studied with traditional angiography. Higher detection rates for AKA localization have been reported with computed tomographic angiography (CTA) and magnetic resonance angiography (MRA), with the latter achieving rates of nearly 100%.[83]

The importance of reimplanting the intercostal arteries identified as supplying the AKA is not universally accepted. Even in patients with an identified and reimplanted AKA, spinal cord injury is not always prevented. Some investigators have concluded that preoperative localization of the AKA has little impact on neurologic outcome after TAA repair. A report[84] found no improvement in overall neurologic outcome with preoperative spinal cord angiography, but it offered important insight regarding the type of aneurysm, identification of the AKA, and neurologic outcome. In patients undergoing TAA repair for extensive degenerative aneurysms, spinal cord injury occurred in 0 of 45 patients versus 10 (12%) of 81 patients with and without an identified AKA, respectively. In contrast, identification of the AKA was not helpful in the case of chronic expanding aortic dissection, with 3 (15%) of 20 patients versus 3 (6%) of 49 patients suffering spinal cord injury with and without an identified AKA, respectively. The investigators hypothesized that mural thrombus in degenerative aneurysms results in the occlusion of many intercostal arteries and favors the development of extensive paravertebral collateral channels (see Fig. 56.10). Identification of an AKA allows focused reimplantation with uniform success. In

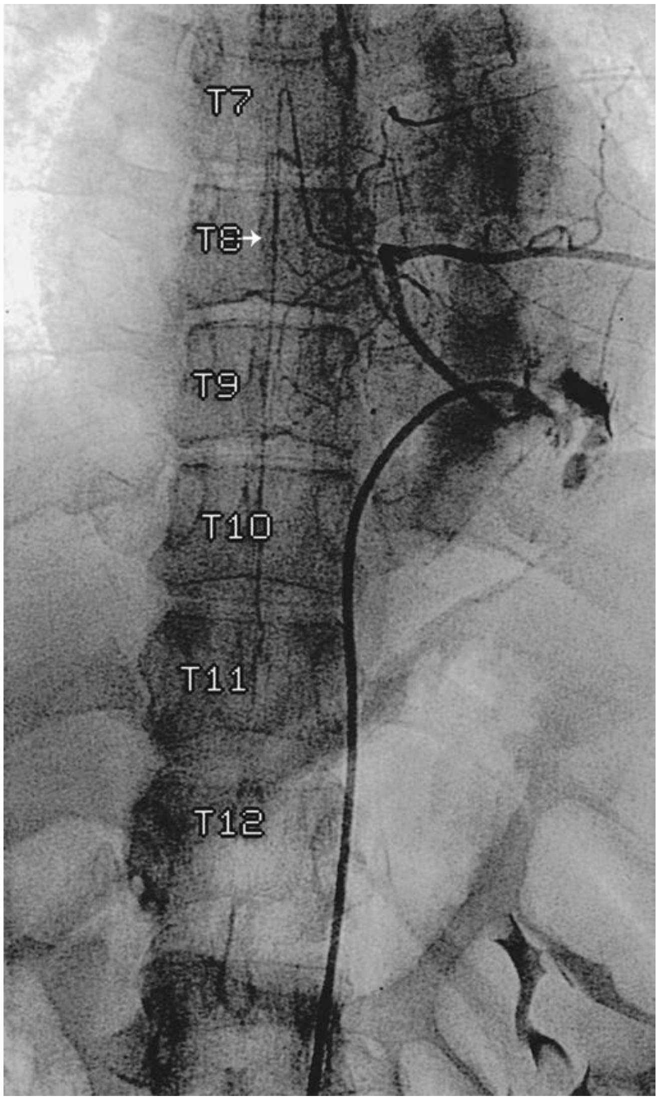

Fig. 56.10 Spinal cord angiogram of an extensive degenerative thoracoabdominal aortic aneurysm. Selective injection of the intercostal artery at T8 *(arrow)* demonstrates the great radicular artery and the extensive paravertebral collateralization.

patients with chronic dissection, most intercostal arteries are patent, collateralization is minimal, and reimplantation of one or two intercostal arteries may be insufficient to supply blood flow to the spinal cord. This collateral blood supply concept is further supported by clinical studies demonstrating that clamping the segmental supplier to the AKA during TAA repair does not produce critical SCI in the majority of patients.[83] Sufficient collateral blood supply, independent of the AKA, must therefore exist to maintain spinal cord integrity.

Delayed-onset neurologic deficits are common after TAA repair.[85] In a large series of 2368 TAA repairs, 93 (3.9%) patients had postoperative paraplegia or paraparesis, 34 (37%) of whom initially had intact spinal cord function but a deficit developed later.[86] Preoperative renal dysfunction, acute dissection, and extent type II TAA are significant predictors of delayed neurologic deficit. Postoperative hypotension and CSF drain malfunction may play an important role in the development of these deficits. Neurologic function can frequently be recovered by maintaining an optimal arterial blood pressure and CSF drainage.

Renal Ischemia and Protection

Renal failure after TAA repair results from preexisting renal dysfunction, ischemia during cross-clamping, thrombotic or embolic interruption of renal blood flow, and hypovolemia and hypotension. Approximately 6% of patients require postoperative dialysis, even in centers with the most clinical experience. The associated mortality can be high. The primary predictor of postoperative renal failure is preoperative renal dysfunction. The duration of cross-clamp time is very important with the clamp-and-sew technique. Retrograde distal aortic perfusion techniques are widely used to preserve renal function during the cross-clamp period. Adequate bypass flow and arterial blood pressure are essential for maintaining renal function. Systemic and regional hypothermia, by reducing O2 requirements, protects the kidneys during ischemia. Some centers advocate the use of DHCA in the treatment of distal TAAs (i.e., extent type III and IV) to preserve renal function.

The role of pharmacologic protection is somewhat controversial. Mannitol 12.5 to 25 g/70 kg is often given before cross-clamping. Mannitol improves renal cortical blood flow and the glomerular filtration rate in animal models of ischemia. Endothelial cell swelling is decreased, and an osmotic diuresis occurs. Evidence demonstrates free radical scavenging with mannitol and subsequent protection from ischemia in animals. Loop diuretics are sometimes given, but these drugs have been less effective than mannitol in experimental models. In clinical studies, the prophylactic use of loop diuretics has not been shown to improve outcome or reduce the need for dialysis for patients with acute renal failure. Dopamine given in low doses (1 to 3 μg/kg/min) dilates renal blood vessels and increases renal blood flow and urine output. Despite these beneficial effects, whether dopamine provides renal protection during ischemia is not clear. Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some promise as a neuroprotective drug; however, there is no evidence to support its routine use.

At the present time, optimal renal protection during TAA surgery should rely on hypothermia, mannitol, and prevention of hypotension and hypoperfusion of the kidneys.

Coagulation and Metabolic Management

Coagulopathy is a frequent complication during TAA repair. A dilutional coagulopathy in which platelets become deficient after approximately one blood volume of replacement develops during massive transfusion (see also Chapters 49 and 50). At between one and two blood volumes of replacement, coagulation factors are diluted to levels low enough to increase bleeding. Other contributing factors are residual heparin; ischemia of the liver, in which most coagulations factors are produced; and persistent hypothermia after weaning from bypass. With the early use of fresh frozen plasma and platelets, severe coagulopathy often can be avoided. The prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count should be measured frequently. Point of care thromboelastography (TEG or ROTEM) can be used as well. Cryoprecipitate may be necessary to correct coagulopathy, especially when the prothrombin time and partial thromboplastin time are prolonged and hypervolemia prevents the administration of significant volumes of fresh frozen plasma. When coagulopathy persists despite these efforts, å-aminocaproic acid or tranexamic acid are beneficial as antifibrinolytic therapy, and desmopressin can be given to increase circulating levels of von Willebrand factor and factor VIII. Normothermia should be achieved by complete rewarming before separation from bypass, by increasing ambient temperature after separation from bypass, and by forced-air warming over the upper body skin surface.

Analysis of arterial blood gases and electrolyte levels should be performed frequently. Hyperkalemia should be treated aggressively, especially in oliguric or anuric patients. Calcium chloride, sodium bicarbonate, insulin, and glucose are the primary acute treatments of hyperkalemia.

Endovascular Aortic Repair Surgery

HISTORY OF ENDOVASCULAR AORTIC REPAIR

The first EVAR of the aorta was performed and reported by the Ukrainian surgeon Dr. Nicholas Volodos and his colleagues. On March 24, 1987, they performed the world's first human endovascular repair of a posttraumatic pseudoaneurysm of the descending thoracic aorta and the patient survived 18 years after the stent graft insertion without any evidence of stent-related complications. However, the case was performed behind the iron curtain, which prevented the news from spreading globally and their work was first published in Russian in 1988.[87]

On September 7, 1990, the Argentinian surgeon Juan Parodi, the Argentinian radiologist Julio Palmaz, and their colleagues performed the first successful EVAR in the western world. After many years of experimenting with stents on dogs with minimal funding, Parodi finally got permission from his institution to perform cases on humans on the condition that these patients had to have been rejected for intervention previously by at least two

centers. In 1990, he received a phone call from the Argentinian president asking him to use his device on his cousin, who had an aortic aneurysm and severe COPD. Parodi went ahead with the operation and it became his first successful EVAR. Three months later, the patient developed a distal endoleak and he was treated by an aorto-uni-iliac endograft, occlusion of the contralateral common iliac, and a femorofemoral bypass. The patient lived for 9 years and died due to pancreatic cancer.[88]

For all types of aortic diseases, endovascular technique is being utilized as the most feasible treatment option and a perfect alternative to treat AAA with the aid of endoluminal devices (Fig. 56.11).[89] Endovascular grafting is being used in diverse types of traumatic injuries, ruptures, aortic dissection, and in the diseases of thoracoabdominal and thoracic aorta. The EVAR is considered as one of the main treatment choices for patients who are affected with AAA because it is a less invasive treatment option, associated with reduced perioperative mortality and morbidity, and requires a short stay at the hospital.[90]

ADVANCEMENTS IN STENT-GRAFT DEVICES

The endovascular technique started in the 1960s on an experimental basis and has progressed through a number of developmental eras that have resulted in EVAR as the most common technique for repair of AAAs. More than 2 decades ago, Parodi and fellow colleagues described the first endovascular repair of an AAA.[91] At that time, endografts for AAAs were being used on patients who had severe surgical risks for an open AAA repair. After analysis and detailed comparison of the developments and advancements in EVAR over the previous two decades, the researchers were able to show considerable success in the procedures, outcomes, and efficiency. These grafts are made up of modular bifurcated devices composed of synthetic fabric which is deployed in the human body through a catheter. After the successful treatments in endovascular repair of the descending aorta, the stents received undeniable success and accolades in cases of the infrarenal aorta. Dake and colleagues, in 1994, provided the first report of using these stent devices for patients with descending thoracic aortic aneurysms.[92] They conducted tests on 13 patients by using self-expanding stent-grafts and reported 100% success, thereby gaining approval of using these stent-grafts by the FDA after a decade in 2005. Since then, the FDA approved many other stent-graft devices for an array of aortic diseases such as traumatic transections, ruptures, penetrating ulcers, dissections, and aneurysms. In 2012, the FDA approved fenestrated stent-grafts for correcting pararenal and juxtarenal aortic aneurysms through endovascular mechanisms.[93] In these devices, the graft fabric openings or scallops are easily aligned with the arteries splitting off the aorta, which significantly paves the way to exclude the aneurysm yet maintain the end-organ perfusion. These fenestrated grafts are referred to as FEVAR, or fenestrated EVAR, whereas the original EVAR name is commonly used to refer to the treatment of infrarenal aneurysms by bifurcated grafts.

It is also worth noting that off-the-shelf stent-grafts are ready-to-go types of stent-grafts used to treat those patients who fall prey to complex AAAs in the acute setting. These standard off-the-shelf fenestrated stent-grafts were studied by the researchers, who found no reported cases of perioperative death, rupture, aneurysm dilation, and stent migration.[94] However, there is still a dearth of significant clinical evidence for the potential benefits of off-the-shelf fenestrated and branched stent-grafts; hence, more research is suggested to support the view that these stents have the true potential of lessening the requirement for perioperative customization of graft for AAA patients. The main difference between the fenestrated grafts (FEVAR) and multibranched grafts (mBEVAR) is that the latter has axially oriented cuffs that serve as routes to cannulate and stent the target mesenteric or renal vessels. This gives surgeons less need for absolute precision to align the scallops of the FEVAR right at the origin of the vessels. It also gives them a small margin of moving safely with the device up or down the aorta. This comes at the expense that the BEVARs tend to be longer devices and end up covering a significant portion of the descending thoracic aorta; hence, the risk of spinal cord injury exists, and spinal cord protection strategies should be considered.[95]

The endovascular approach is the best alternative, as it is devoid of open incisions, considerable fluid shifts and blood loss, wide dissections, and long aortic cross-clamp times as in open repairs. Careful attention must be given in choosing the optimal treatment strategy for patients with AAAs. The endovascular technique involves the placement of the endovascular stent graft based at the level of the disease and the size of the vessel. The femoral arteries are accessed either by cutdowns or percutaneous punctures. In general, smaller devices are available commercially that are used percutaneously for EVARs, FEVARs and BEVARs. The decision to do a cutdown versus a percutaneous access depends on the size of the device used, the size of the femoral arteries, preexisting femoral or iliac diseases or surgeries, and the surgeon's experience. If the patients have critically diseased iliac or femoral arteries, then they may need a concomitant, local endarterectomy or balloon angioplasty. Additionally, during the endovascular AAA, around 20% patients are recommended to undergo adjunctive retroperitoneal procedures where the common iliac artery is exposed by a retroperitoneal approach to place a synthetic iliac conduit. The same iliac conduit is used to endoluminally place the delivery system into the aorta. Beyond any reasonable doubt, these adjunctive retroperitoneal procedures allow a significant number of patients to experience EVAR, though these procedures are not free from longer hospital stays, lengthy procedure time, and extensive blood loss because of their hybrid nature.[96]

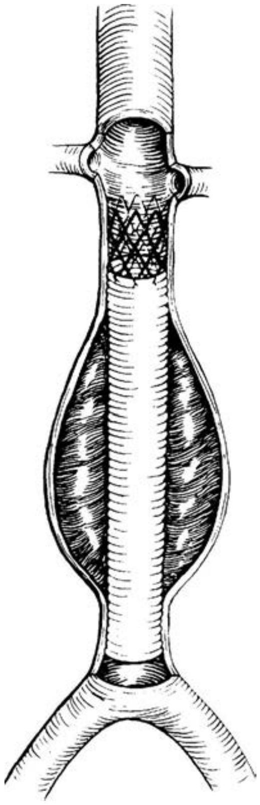

Fig. 56.12 Graft-stent combination with cephalic stent. (From Yao JST, Eskandari MK. Transfemoral intraluminal graft implantation for abdominal aortic aneurysms: two decades later. *Ann Vasc Surg*. 2012;26[7]:895–905.)

Understanding the surgical approach and vascular access is important to tailor the anesthesia plan. Most EVARs today are done via percutaneous access of the femoral arteries, which makes monitored anesthesia care (MAC) with local infiltration to the access site a viable safe alternative (Figs. 56.12 to 56.14). On the other hand, multibranched grafts are much bigger devices and the procedure takes much longer, as it often involves cannulation of the visceral branches. Cannulation of caudally oriented vessels, as the celiac axis and the superior mesenteric arteries, is easier if performed via a left axillary artery access. However, today there are deflectable, steerable guiding sheaths that allow the surgeon to cannulate the caudally oriented vessels from the same femoral access used for insertion of the aortic component, without the need for an additional arterial cutdown in the left arm.

ANESTHETIC MANAGEMENT

To sketch the anesthetic management options associated with EVAR, it is worth mentioning that in the past, the long

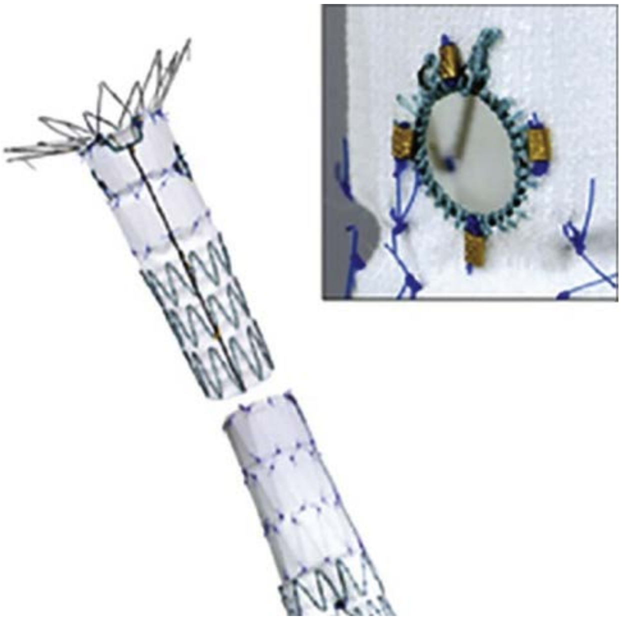

Fig. 56.13 Customized fenestrated stent-graft. (Modified from Kothandan H, Chieh GLH, Khan SA, et al. Anesthetic considerations for endovascular abdominal aortic aneurysm repair. *Ann Cardiac Anaesthesia.* 2016;19[1]:132.)

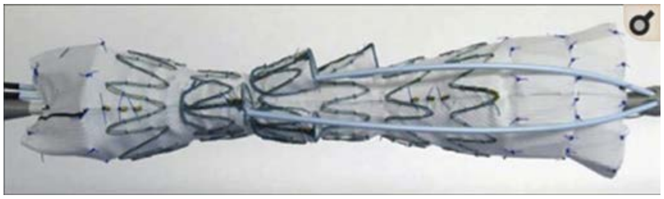

Fig. 56.14 Customized branched stent-graft. (From Kothandan H, Chieh GLH, Khan SA, et al. Anesthetic considerations for endovascular abdominal aortic aneurysm repair. *Ann Cardiac Anaesthesia.* 2016;19[1]:132.)

surgical procedures used general anesthesia. But with the passage of time, surgical procedure times were reduced, and procedures started changing due to the inclusion of newer generation devices. The local and regional anesthetic techniques were employed with IV sedation. Despite the significant use of local, regional, and general anesthesia, conflicting reports raised their voices concerning anesthetic management. According to a report, the regional or local anesthesia might decrease the hospital stay time, ICU admission, and reduce early complications.[97] Anesthesiologists must consider things like a patient's functional status, co-morbidities, aneurysm complexity, and surgical urgency. According to Kothandan and associates, when it comes to examining a unique risk stratification model in endovascular surgery scenarios, there is no single useful model.[97a] Few anesthesiologists take leverage of the *risk scores* in this context, such as revised *cardiac risk index* or the modified *customized probability index* when they are engaged in endovascular surgery scenarios.[98,99]

Spinal Cord Blood Supply

It is critically important to get an overview of the spinal cord blood supply since it has a complex anatomy, but the latest imaging technology has expanded the very small and complex vessels to a significant degree. Hence, it is now easier to determine the SC vascular pattern as compared to the past, as explained above in the open thoracoabdominal repair section. To better understand the blood supply to the spinal cord, it is important to adapt the collateral network concept. The concept can be summarized as follows:

- There is an axial network of arteries that supply the spinal cord and run in the paravertebral tissue.
- Input to this axial network comes from segmental arteries, subclavian arteries, and hypogastric arteries.
- Blood supply to the cord can increase from one source when another is compromised. An example of this steal phenomenon is the back bleeding from intercostals into an open aortic sac after aortic cross-clamping.[100]

This extensive spinal cord arterial system thus consists of an extrinsic and an intrinsic vascular system. The extrinsic network consists of segmental vessels arising from the intercostal and lumbar arteries, subclavian arteries, and the hypogastric arteries. The intrinsic network which receives supply from the extrinsic network is formed by the two posterior spinal arteries supplying the posterior region of the cord and a single anterior spinal artery supplying the anterior region of the cord (Fig. 56.15). The posterior spinal cord is relatively protected from ischemia because the collateral blood flow from the two posterior spinal arteries compared to a single anterior spinal artery make the anterior portion of the cord more susceptible to ischemia. The anterior spinal artery originates from the terminal branches of both vertebral arteries and courses along the anterior longitudinal fissure of the spinal cord receiving reinforcing blood supply from the radicular or segmental medullary branches, the branch of the posterior intercostals, or the lumbar arteries. The largest of the anterior segmental branches is the AKA, which supplies a large portion of the caudal two thirds of the anterior spinal artery. Because it is the only major artery supplying this zone, it is susceptible to watershed ischemia. The AKA originates from a left posterior intercostal artery off the descending aorta usually between T9 and T12 but has originated in some instances from lower level up to L5. A unique identifying feature of the AKA is the "hairpin configuration" on imaging that can be explained by the differential growth of the spinal cord and vertebral column during embryologic development.

Anterior spinal cord syndrome happens due to infarction of the portion of the spinal cord supplied by the anterior spinal artery. This may happen due to disruption of the AKA or the anterior spinal artery itself at the thoracoabdominal levels. Etiologies may vary between aortic dissection, emboli, covering of large segments of the thoracoabdominal aorta by endovascular stents, and surgical dissection during repair of thoracoabdominal aortic aneurysm (TAAA). The clinical presentation of the syndrome will depend on the spinal cord tracts and the level of cord injury. Classically, the anteromedial portion of the cord which contains the corticospinal and the corticobulbar tracts receives blood supply only from the anterior spinal artery, leading to motor paralysis below the level of injury if this supply is disrupted. The anterolateral aspect of the cord contains the

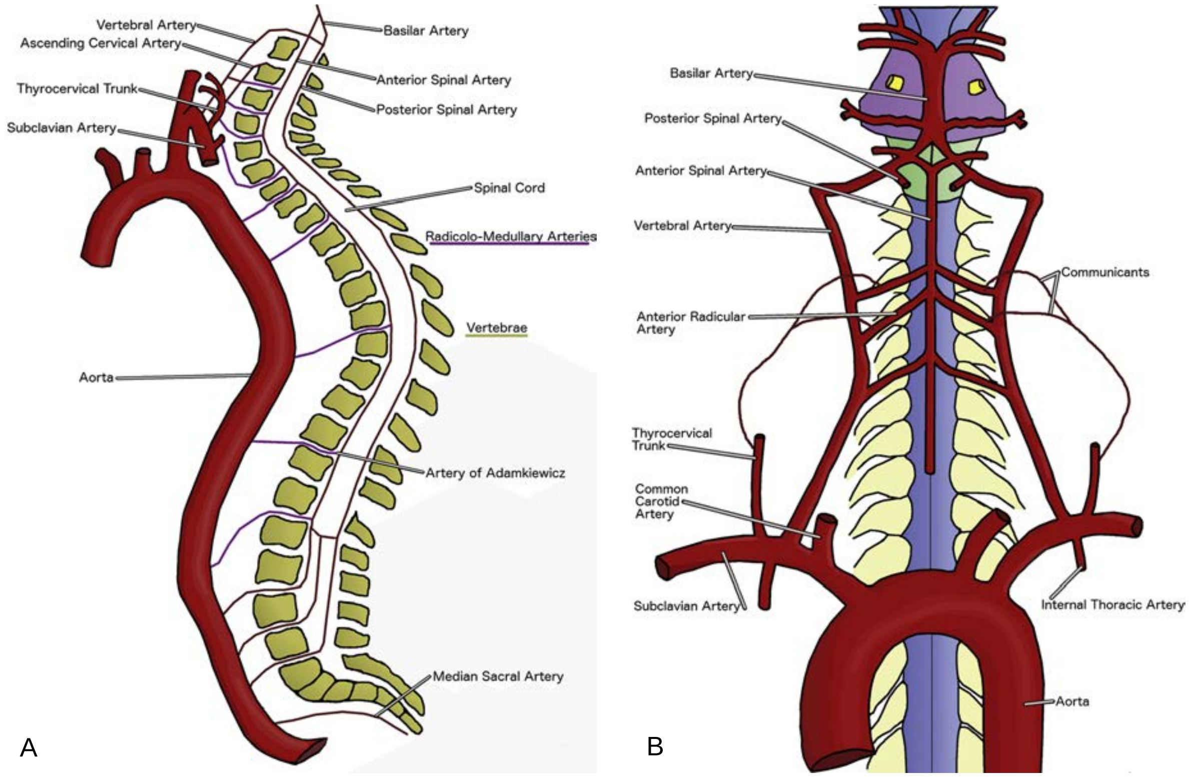

Fig. 56.15 An overview of blood supply to the spinal cord and the cervical spinal cord and the origin of the anterior spinal artery. (A) An overview of blood supply to the spinal cord. The spinal cord predominantly receives blood from three arteries originating around the cervical-cranial junction. These arteries run longitudinally along the spinal cord, terminating at the caudal end. These three arteries, the anterior spinal artery, and paired posterior spinal arteries, receive their blood supply mainly from the vertebral arteries, as well as the ascending cervical arteries, branches of the thyrocervical trunk. The thyrocervical trunk additionally supplies the cervical spinal cord via numerous anterior and posterior radiculomedullary arteries. These arteries do not anastomose with the spinal arteries *(anterior and posterior)*; rather, they directly supply the spinal cord at the level they enter the vertebral canal. As the spinal cord extends caudally, blood supply becomes scarce. Anterior and posterior radiculomedullary branches from the thoracic and abdominal aorta continue to supply the spinal cord directly, but the spinal arteries do not receive any new anastomoses until the artery of Adamkiewicz at the level of the lower thoracic or lumbar vertebrae. The lumbar and sacral spinal cord additionally receives blood from the median sacral artery anteriorly. Magenta lines represent radiculomedullary arteries and yellow boxes represent vertebrae. (B) The cervical spinal cord and origin of the anterior spinal artery. The anterior spinal artery originates from the vertebral arteries around the level of the cervical-cranial junction. Additionally, the anterior spinal artery receives blood from the anterior radicular arteries (branches of the vertebral arteries) and the ascending cervical arteries (branches from the thyrocervical trunk). Following these original tributaries, the anterior spinal artery does not receive blood from any other anastomosis until the lower thoracic and lumbar areas via the Artery of Adamkiewicz (not shown). The anterior spinal artery supplies the bulk of oxygenated blood to the anterior spinal cord. (From Hoehmann CL, Hitscherich K, Cuoco JA. The artery of Adamkiewicz: vascular anatomy, clinical significance and surgical considerations. *J Cardiovasc Res*. 2016;5:6.)

spinothalamic and the spinocerebellar tracts, a watershed area that receives blood supply from both anterior and posterior spinal arteries, but it can still be infarcted in anterior spinal cord syndrome, affecting pain and temperature sensation. The dorsal columns responsible for vibratory sensation and proprioception remain intact, as they are usually supplied by the posterior spinal arteries. Patients with anterior spinal cord syndrome could also present with autonomic dysfunction as bowel and bladder incontinence, orthostatic hypotension, and sexual dysfunction.[101]

Anesthesia Roadmap for EVARs

Anesthesia administration mainly focuses on

- Hemodynamic stability of the patient
- The preservation of perfusion to the key organs such as splanchnic vessels, kidney, spinal cord, heart, and brain
- Early identification and management of blood loss and maintaining intravascular volume
- Maintaining the normal core body temperature (perioperative normothermia)

Karthikesalingam and associates argue that there is very little evidence indicating the best anesthetic technique in the case of standard EVAR, and even more limited evidence in the case of complex EVAR,[102] because most of the literature relies on the retrospective and descriptive studies. Therefore, the selection of feasible technique should be based on several factors that include aneurysm complexity, patient's premorbid state, vascular team experience, choice of anesthesiologist, and the patient. Fleisher and associates favor the opinion that there is not a particular mode of anesthesia administration on cardiac disease patients in the ACC/AHA guidelines, because there is no sufficient evidence available in this regard.[18] It is not very common that the surgery turns into open repair scenario (the rates are less than 2%), yet the anesthesiologist should always be ready for such intraoperative rupture with massive blood loss by having adequate vascular access.[104] The following checklist provides an anesthesia roadmap that the clinician can refer to when considering how to proceed with endovascular aortic procedures.

1. Choice of Anesthesia
2. Radiation Safety
3. Renal Protection Vascular Access and
4. Blood Loss
5. Temperature Control
6. Spinal Cord Protection

CHOICE OF ANESTHESIA

In 2015 Broos and associates studied the anesthesia choices, such as general, regional, or local, by reviewing the outcomes of EVAR repairs. They concluded that the choice of anesthesia was independent of perioperative morbidity and mortality.[105] At the same time, the local or regional anesthesia has an upper edge over general anesthesia in terms of postoperative hospital stay, ICU stay, and shorter procedure times. Edwards and associates examined the results of 6009 elective EVAR procedures against the anesthetic procedures such as local/ MAC, regional, and general anesthesia.[106] They concluded that general anesthesia was strongly linked with pulmonary morbidity and increased hospital stays after the EVARs when compared with local/ MAC and spinal cord anesthesia. Similarly, Karthikesalingam and associates conducted a systematic review and meta-analysis of 10 studies comprising of 13,459 patients who had EVAR surgeries under the administration of local or general anesthesia.[102] They also reported that the group associated with local anesthesia had less postoperative complications and shorter postoperative hospital stays and procedure times when compared to the group associated with general anesthesia. Despite those retrospective studies and systemic reviews, current literature still lacks evidence based on randomized prospective data. Also, the continuous change is the commercially available devices and the increase in surgical experience with endovascular repairs, both of which lead to a composite decrease in operative times, today much less than when the initial endovascular aortic trials were performed.

The point is that there is no substantial evidence which proves that one anesthetic technique has an upper hand over another, and similarly, EVAR success does not point toward using any specific type of anesthesia, either. Generally speaking, simple EVARs performed through percutaneous punctures of the groin can be done under local anesthesia and MAC, neuraxial anesthesia, or general anesthesia provided that there is no other contraindication for the choice of anesthesia. More complex endovascular repairs, like FEVARs or BEVARs, that require multiple arterial cutdowns or combined groin and arm access will require general anesthesia.

Radiation Safety

Endovascular procedures are gaining much more popularity on the score that they exhibit lower access site-related blood loss, but at the same time, the patients become vulnerable to radiation exposure risk as well.[107] In this regard, the key principle of "As low as reasonably achieved" (ALARA) remains the bedrock foundation to limit the staff and patient's exposure to radiation accordingly.[108-110] In this regard, the clinician can take leverage from real-time radiation monitoring procedures so that he is aware of the situation and can adjust the radiation dose.[111]

Renal Protection

Contrast-induced nephropathy (CIN) is renal function impairment associated with a baseline increase in serum creatinine concentration of 25% or more or an absolute increase of 0.3 to 0.5mg/dL within 2 to 3 days of administration of IV contrast.[112]

The recently published PRESERVE Trial, which was a 2-by-2 factorial design, double blinded, placebo and comparator drug controlled randomized study, was conducted to answer the question of whether the outcomes changed after angiography with sodium bicarbonate and acetylcysteine in patients at high risk for CIN. The study concluded that there was no benefit for intravenous sodium bicarbonate over intravenous sodium chloride, nor for acetylcysteine over placebo in prevention of death, need for dialysis, persistent decline in kidney function at 90 days, or for the prevention contrast-induced acute kidney injury.[113]

The two most important factors that contribute to CIN are the contrast load and the preexisting kidney disease. Limiting the contrast load, and adequate hydration to decrease the viscosity of the iodine-based dyes, thus decreases the oxidative stress exerted on the proximal convoluted tubules.

Vascular Access and Blood Loss

The surgeons normally use either axillary or left brachial access for the insertion of snorkels or visceral stents of the FEVARs. Cheng underlines that there are specific challenges in anesthetic management scenarios such as prevention of paraplegia and stroke and blood pressure control.[114] Apart from this, the surgeons might need to perform bilateral femoral cutdowns as well as left axillary access. This would leave one limited option (i.e., right arm for intraaortic balloon pump [IABP] access). A central venous access is not a must but would be used when complex branched grafts are used with multiple comorbidities and limited peripheral venous access. Lengthy procedures like branched grafts are performed under anticoagulation with heparin. This creates a potential of continuous slow blood loss from the multiple arterial cutdown sites that could be overlooked in the dark hybrid rooms. It is not very common to experience sudden hemodynamic instability in patients unless there is a ruptured aneurysm or an aortic occlusion balloon is being used.

Temperature Control

The patient is vulnerable to perioperative hypothermia with adverse outcomes due to many untoward physiologic effects. Hence, maintaining normothermia is highly recommended and needed before the skin incision process. This could be accomplished by enhancing the operating room's ambient temperature, by using warming IV fluids, and by using radiolucent underbody warmers. Hypothermia could delay tracheal extubation, which is sometimes preferred to be as early as possible to perform a neurological exam if there are risks of strokes or spinal cord injury.

Spinal Cord Protection

SCI remains one of the devastating possible complications of thoracic and thoracoabdominal aortic repair.[115,116]

There could be many reasons for the occurrence of SCI such as occlusion risk of stent grafts associated with the AKA, considered the main collateral artery, or due to damage of middle sacral arteries, inferior mesenteric arteries, or internal iliac arteries. Risk factors for spinal cord injury include emergency surgery, aortic dissection, extensive aortic disease, aortic rupture, prior abdominal surgery, hypogastric artery occlusion, and history of renal dysfunction. Therefore, many strategies are utilized such as arterial pressure augmentation, CSF drainage, and lowering the CVP.[117] The 2014 European guidelines on the management of aortic disease stated that CSF drainage can be beneficial in high-risk patients (class IIa, level of evidence C).[118] Similarly, the ACCF/AHA guidelines for the thoracic aortic disease recommended CSF drainage in TEVAR patients who are at high risk for spinal cord injury (class I, level of evidence B).[119] Spinal drains may be placed preinduction of general anesthesia or postinduction if the patient cannot tolerate the procedure. For patients receiving anticoagulant or antiplatelet therapy, the American Society of Regional Anesthesia and Pain Medicine (ASRA) Guidelines should be followed, and the perioperative management of those medications should be arranged with the perioperative team.[120]

To optimize spinal cord perfusion, CSF pressure is usually monitored and CSF periodically drained. Most institutions have their protocols for management of spinal drains and CSF drainage. Most local guidelines and protocols advocate for CSF pressure of 10 to 15 mmHg. Some institutions drain CSF periodically during the intraoperative and postoperative periods while others drain according to CSF pressure or if there are any signs of SCI. Care should be taken to avoid over-draining CSF. Excessive rapid CSF drainage, particularly during the intraoperative period of heparinization or postoperative coagulopathy, could lead to intracranial hypotension and increase the risk of intracranial hemorrhage.

If bloody CSF is encountered during the placement, discussion with the surgeon and the patient if the placement was attempted preinduction, and rescheduling an elective case should be considered. Some institutions encourage routine fluoroscopic-guided spinal drain insertion to decrease the number of passes. Ultrasound-guided placement could be considered.

Other measures to decrease the risk of SCI is the maintenance of flow through the left subclavian artery and the internal iliac arteries. Subclavian artery flow can be decreased if a TEVAR graft covers the origin of the left subclavian. Flow can be increased by a partial arch debranching through a left carotid to a left subclavian bypass. In the case of internal iliac arteries, minimizing the occlusion by large introducer sheaths will improve the spinal collateral flow.[121]

POTENTIAL COMPLICATIONS

Early and Late Complications

The early complications are those that occur from day 2 to day 30 after the surgery. These types of complications include postimplantation syndrome (PIS), paraplegia, stroke, acute renal failure, lower extremity and pelvic ischemia, aneurysm rupture, and others. The late complications that occur 31 days after surgery are associated with endoleak, but they also include the aneurysm rupture, its elongation, degenerated proximal neck, device migration, limb occlusion, and graft infection.

Endoleaks

EVARs are vulnerable to a condition where the aneurysm sac experiences arterial blood flow, despite the exclusion by the stent graft, and is thereby unable to maintain or accomplish full exclusion from the blood flow (Figs. 56.16 and 56.17). Chen and Stavropoulos explain the type 1 endoleak where the stent-graft fails to accomplish a circumferential seal at the distal (IB) or the proximal (IA) positions, thereby demanding immediate treatment due to aneurysm sac systemic pressurization.[122] If not treated promptly, it can result in either expansion of the aneurysm or even rupture. An increased occurrence of IA needs early endovascular intervention and can occur with hostile proximal aortic neck anatomy. There are certain technologies which can detect these endoleaks, such as cone-beam computed tomography. Endoleaks are normally treated by balloon angioplasty of the proximal attachment site so that the desired seal is obtained through remodeling of the stent-graft. The endoleak can also be bridged by covered extension of the native endograft.[123] Embolization is another treatment option specifically when the space between the renal arteries and the endograft is not adequate. Fenestrated or branch graft extensions are also an alternative for more complex proximal endoleaks.

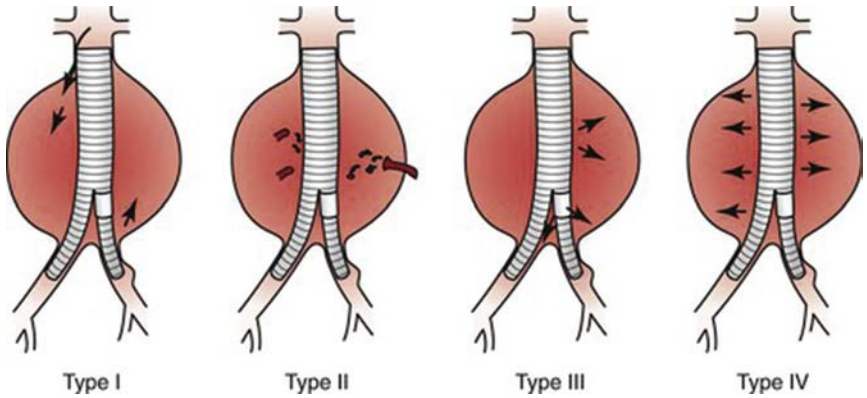

Fig. 56.16 Endoleak types. (From White GH, May J, Waugh RC, et al. Type III and type IV endoleak: toward a complete definition of blood flow in the sac after endoluminal AAA repair. *J Endovasc Ther*. 1998;5:305–309.)

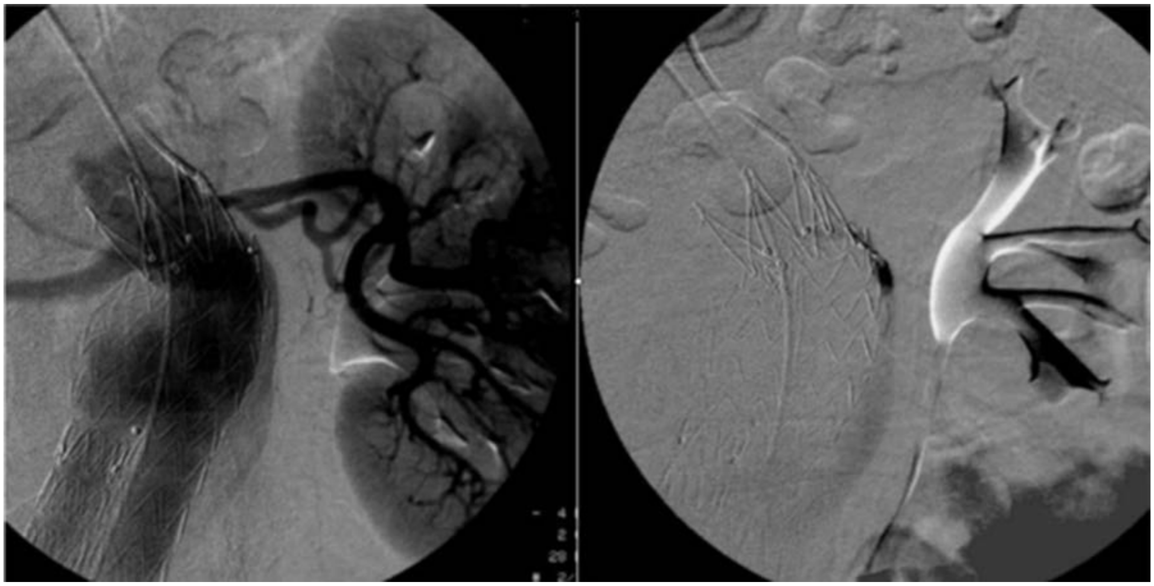

Fig. 56.17 Computed tomography scan performed 2 days after endovascular aneurysm repair revealing a progressively enlarging type 1A endoleak. (From Tureli D, Baltacioglu F. Type I endoleak management after endovascular repair of infrarenal abdominal aortic aneurysm. *Vasc Dis Manag.* 2014;11:E91–E97.)

Type II endoleak occurs when the aneurysm sac undergoes reverse filling from the branch vessels through either lumbar or inferior mesenteric arteries.[124,125] This can result in various anomalies such as aneurysm rupture, sac enlargement, and enhanced intrasac pressures.[126] Type II endoleaks can be treated by transarterial embolization through the iliac arteries or retrograde embolization through the superior mesenteric or inferior mesenteric arteries. They can also be treated by translumbar computed tomography angiogram (CTA)-guided embolization.[127] A transcaval approach can be used if the type II endoleak is close to the IVC. A transjugular sheath is advanced through the IVC and a needle is used to access the aneurysm sac to embolize it. Potential risks of such procedure include retroperitoneal bleeding, pulmonary embolization from non-targeted embolization, and aortocaval fistulas.[128]

Type III endoleaks trigger when the stent-graft undergoes a structural failure, thereby causing the blood flow to move into the aneurysm sac. These endoleaks occur either due to device failure such as detachment of modular graft components, a junctional leak, or due to erosion of fabric. They also require immediate intervention and treatment to avoid the risk of rapid expansion and rupture of aneurysm. These endoleaks are treated by inserting a new fabricated stent graft over the faulty position with angioplasty so that the desired seal is accomplished. The type IV endoleak is associated with graft porosity while Type V endoleak shows the aneurysm sac enlargement which is devoid of any demonstrable trace in the imaging procedures.

Open surgical treatment remains an option if endovascular treatment of endoleaks fails or is not possible. Surgical treatment could range from ligation of offending arteries feeding an endoleak to graft excision and open aneurysm repair with exogenous graft. Careful preoperative planning between the anesthesia and surgical teams requires all to be ready for the possibilities of rupture of the sac intraoperatively or conversion into an open surgery if endovascular treatment fails.

Postimplantation Syndrome

PIS is a poorly understood phenomenon that could occur after endovascular aortic procedures and varies widely in incidence and clinical presentation. Possible explanations could be a sort of systemic inflammatory response syndrome (SIRS) in response to the instrumentation of the vascular endothelium or to the stent graft material. Clinical presentation could include a combination of fever, leukocytosis, thrombocytopenia, and coagulopathy. Treatment should be supportive treatment, especially with antipyretics, platelets, or fresh frozen plasma transfusions to treat the coagulopathy.[129]

Hybrid Arch Repairs

Since the introduction of thoracic endovascular aortic repair (TEVAR) in the early 1990s,[130] the less invasive endovascular approach to descending and thoracoabdominal aneurysms has been advanced with the commercial availability of different types of thoracic stent grafts. Related to the morbid invasiveness and complexity of open arch surgical techniques, hybrid aortic arch repairs have been developed incorporating the use of TEVAR with a conventional elephant trunk repair, or combined with an open debranching of the cerebral vessels, frequently in combination with extraanatomical bypasses.[131,132] This has simplified aortic arch reconstruction and made aortic arch repair feasible in high-risk individuals with comorbid conditions. Aortic arch pathology is also amenable to TEVAR but often requires a concurrent or staged open debranching procedure such as carotid-carotid or carotid-subclavian bypass. Debranching permits stent deployment across the origins of the arch vessels while maintaining perfusion to the head and upper extremities.[133]

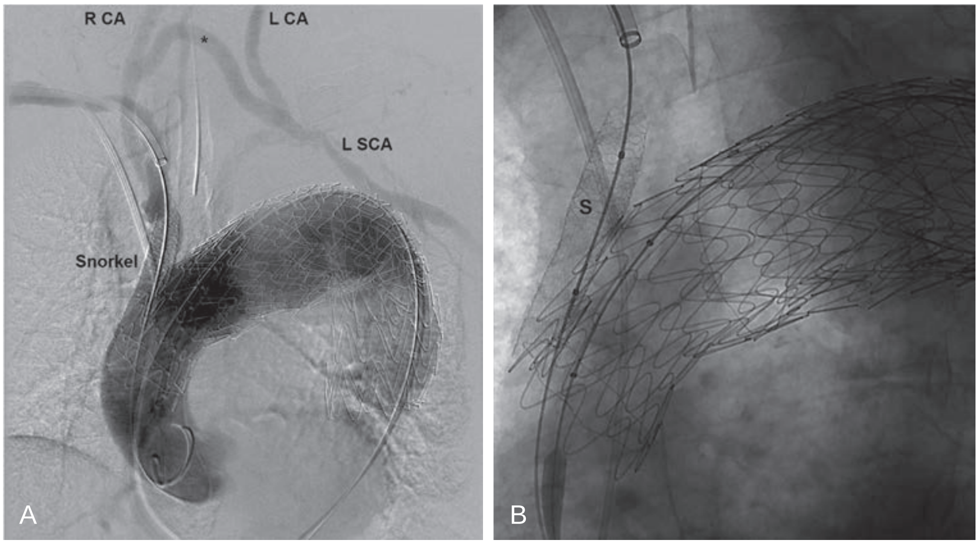

Fig. 56.18 Intraoperative digital subtraction angiography showing completed thoracic endovascular aortic repair with arch debranching after stent deployment with rapid ventricular pacing (RVP). (A) Overview of arch revascularization showing arch stent graft, innominate artery snorkel stent, and carotid-carotid-subclavian bypass (denoted by asterisk). Right common carotid artery *(R CA)*, left common carotid artery *(L CA)*, and left subclavian artery *(L SCA)* are labeled. The temporary pacer wire used to deliver RVP is visible entering the image from the top left. (B) Close-up of snorkel stent *(S)* extending from the ascending aortic arch into the innominate artery. The snorkel stent maintains flow to the carotid and subclavian arteries and allows deployment of a stent graft with proximal landing zone zero. (From Bokoch MP, Hiramoto JS, Lobo EP, et al. Rapid ventricular pacing for landing zone precision during thoracic endovascular aortic arch repair: a case series. *J Cardiothorac Vasc Anesth*. 2017;31[6]:2141–2146.)

ANESTHETIC MANAGEMENT OF HYBRID ARCH REPAIRS

Anesthetic management of TEVAR must facilitate precise deployment of stents at short proximal landing zones near the arch vessels.[134] Deployment is complicated by the hydrodynamics of aortic blood flow that force the stent distally (windsock effect). Depending on the proximity of the planned stent graft to the left ventricular outflow tract, transient hypotension (systolic blood pressure of 60 mmHg) may be highly beneficial during deployment to limit stent migration. Various drugs have been used for this purpose,[135] but rapid ventricular pacing (RVP) is usually the preferred technique (Fig. 56.18).[136] RVP is reported to produce more profound hypotension more quickly, and with shorter duration as compared to sodium nitroprusside.[137,138] While adenosine has been used for transient asystole in the setting of TEVAR and intracranial procedures, an unpredictable duration of asystole and wide individual variation in dose requirement (0.3 to 41 mg/kg) have been reported. Unexpected return of left ventricular contractions can complicate stent deployment at a critical moment. Unlike pharmacologic techniques, the onset and duration of RVP can be controlled precisely. The bulk of published data on RVP arises from the transcatheter aortic valve replacement (TAVR) literature, in which RVP is utilized during balloon valvuloplasty and valve deployment. Small studies have shown efficacy and safety of RVP for TEVAR, but deaths have been reported (Fig. 56.19).[139]

Fig. 56.20 illustrates the hybrid aortic arch repair types I, II, and III.

Hybrid approaches for the treatment of aortic arch aneurysmal pathology are being performed with increasing frequency. This reflects the increasing comfort level of the surgeons with endovascular technology, and the improving technology of endovascular platforms to successfully land stent grafts in the proximal thoracic aorta. As the patient population with thoracic aortic disease seeking intervention get older, embracing and honing these skills will be crucial. In addition to the associated operative mortality of complex operations such as aortic arch hybrid procedures, the Achilles heel of this intervention remains neurologic complications. Several groups have shown that arch hybrid procedures can be performed with acceptable mortality, with very minimal postoperative and long-term endoleak rates. Neurologic complications, including stroke and SCI, remain significant causes of morbidity and associated mortality.[140]

Carotid Endarterectomy

The strong association between stroke and carotid artery disease is well known. The principal cause of carotid artery disease is atherosclerosis, which most commonly involves the bifurcation of the common carotid artery with frequent extension into both the internal and external carotid arteries. The clinical manifestations of carotid artery disease represent a spectrum of conditions, with fatal or debilitating stroke secondary to cerebral infarction at one end of the spectrum and ranging successively through non-debilitating stroke, transient ischemic attack, and amaurosis fugax (transient attack of monocular blindness) to an asymptomatic bruit. Cerebrovascular sequelae of carotid atherosclerosis may result either from embolization of thrombus or atheromatous debris or from a reduction in flow (hypoperfusion) secondary to stenosis. The latter probably accounts for less than 10% of the cerebrovascular sequelae of carotid atherosclerosis. Although much is known about the genesis and evolution of atherosclerosis, significantly less is known about the circumstances that lead to plaque instability and rupture. Regardless of the mechanism, the degree of

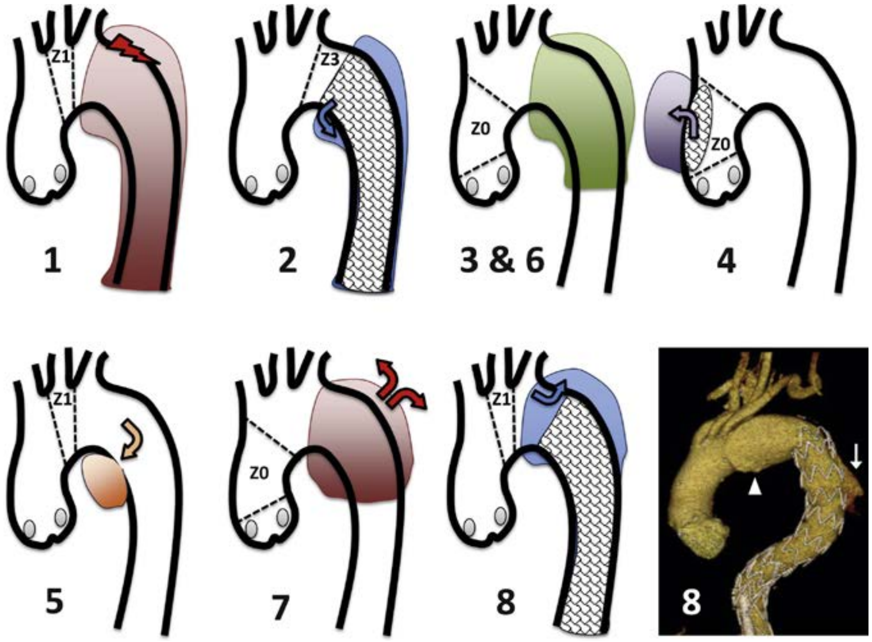

Fig. 56.19 Schematic of aortic arch pathology in patients undergoing thoracic endovascular aortic repair (TEVAR) with rapid ventricular pacing (RVP) in this study. (Patient #1) Aneurysm with chronic type-B dissection, (#2) aneurysm enlarging due to endoleak after prior TEVAR, (#3 and #6) isolated arch aneurysm, (#4) ascending aortic pseudoaneurysm due to leaking patch at prior aortic cannulation site from coronary artery bypass grafting, (#5) penetrating atherosclerotic ulcer of the aortic arch, (#7) ruptured aortic arch aneurysm, and (#8) enlarging aortic arch aneurysm and endoleak after prior TEVAR. Dashed lines indicate landing zone (Z) for proximal margin of stent deployed under RVP. Arrows indicate leak or extravasation of blood. Lightning bolt indicates dissection. *(Bottom right)* Preoperative three-dimensional reconstructed computed tomography angiogram for patient #8 showing aneurysmal dilation *(arrowhead)* and endoleak *(arrow)*. cerebral injury depends on such factors as plaque morphology, characteristics of the embolus, duration of hypoperfusion, cerebrovascular vasoreactivity, integrity of the circle of Willis, and cerebral collateral circulation. A multi-society guideline is available for the management of carotid artery disease.[141]

Stroke is a major public health burden worldwide. It is the fifth leading cause of death and the leading cause of serious, long-term disability in the United States. Stroke is also a major contributor to health care costs. The direct and indirect costs of stroke in the United States in 2008 are estimated at $65.5 billion.[142] Approximately 780,000 people experience a new (≈600,000) or recurrent (≈180,000) stroke each year in the United States.[142] Annually, more than 95,000 hospitalizations and 165,000 deaths occur from stroke. Well-defined risk factors exist in patients with stroke, the most important of which is hypertension. Approximately 83% of strokes are ischemic (i.e., cerebral thrombosis or embolism), and 7.6% of ischemic strokes result in death within 30 days of initial evaluation.[143] Extracranial atherosclerotic disease accounts for up to 20% of all ischemic strokes. Less than 20% of strokes are preceded by a transient ischemic attack. Despite a well-documented decline in stroke mortality, the annual incidence rate of stroke may be increasing. This increase is probably due to growth in high-risk populations. The incidence of perioperative stroke in unselected patients, patients with asymptomatic carotid bruit, and patients with at least 50% carotid stenosis undergoing general anesthesia and surgery is approximately 0.1%, 1.0%, and 3.6%, respectively.

Although treatment options to reverse the effect of acute ischemic stroke are limited, outcomes may be improved with appropriate therapy. One approved therapy is IV recombinant tissue plasminogen activator (rtPA). Given the narrow 3- to 4.5-hour treatment window from the onset of symptoms, prompt evaluation and diagnosis of ischemic stroke are critical. The addition of endovascular treatment options has improved outcomes. Three randomized controlled trials published in 2015 demonstrated a clear benefit of the addition of clot retrieval compared to standard therapy with thrombolysis. The 2015 American Heart Association/American Stroke Association guidelines now recommend endovascular treatment in acute ischemic stroke if the patient meets criteria (large vessel anterior circulation occlusion, independent at baseline, treatment within 24 hours.)[144]

INDICATIONS

Endarterectomy of the carotid bifurcation has been used to reduce symptoms and prevent stroke for more than 50 years. Although the efficacy of carotid endarterectomy for prevention of ipsilateral stroke in patients with and without symptoms has been demonstrated in large-scale randomized clinical trials,[145,146] multiple factors including perioperative risk, comorbidities, and life expectancy must be considered in the overall assessment. In centers of excellence, it is a low-risk procedure with excellent long-term durability. Carotid endarterectomy is the most common peripheral vascular surgical procedure performed in the United States, with an estimated 130,000 procedures performed annually. The rate and number of carotid endarterectomies have fluctuated significantly since the early 1970s. With marked growth in the specialty of vascular surgery and an expanding list of surgical indications, the number of carotid endarterectomies performed in nonfederal hospitals increased from 15,000 in 1971 to 107,000 in 1985 and then declined substantially over the next 5 to 6 years. The decline was probably due to publications questioning the indications for the procedures and isolated reports citing excessively frequent rates of operative morbidity and mortality.

In 1992, a marked increase in the number of carotid endarterectomies occurred after the results of two large-scale, prospective randomized trials were published. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial both reported definitive results for symptomatic patients with high-grade carotid stenosis (70% to 99%).[145,147] In NASCET, follow-up at 2 years showed a stroke rate for surgical patients of 9% versus 26% for medical patients. This benefit of carotid endarterectomy has persisted at 8 years of follow-up.[148] In the European Carotid Surgery Trial, the long-term stroke rate was 2.8% for surgical patients, excluding a perioperative stroke and death rate of 7.5%, and 16.8% for medically managed patients.

The efficacy of carotid endarterectomy in asymptomatic patients with carotid stenosis has been evaluated in five randomized trials.[146,149-152] The Carotid Artery Surgery Asymptomatic Narrowing Operation Versus Aspirin trial, the first to publish its results, concluded that carotid endarterectomy was not indicated for asymptomatic patients with 50% to 90% carotid stenosis.[149] Unfortunately, this study was seriously flawed and the results questioned. The Mayo Asymptomatic Carotid Endarterectomy Study was terminated early because of a significantly increased number of MIs and transient cerebral ischemic events in the surgical group.[150] Most of these events were not related to the surgery itself but rather to the absence of aspirin in the surgical group. The Department of Veterans Affairs trial was designed to compare the effects of carotid endarterectomy plus aspirin versus medical treatment (i.e., aspirin) in asymptomatic male patients with 50% or greater carotid stenosis.[151] This trial demonstrated a significant reduction in ipsilateral neurologic events in the surgical group (8%) versus the medical group (20.6%). However, the combined incidence of stroke and death was not different between study groups. The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated that patients with asymptomatic carotid stenosis (≥60%) who were treated with carotid endarterectomy and aspirin have a reduced 5-year risk for ipsilateral stroke compared with patients treated with aspirin alone (5.1% vs. 11.0%).[146] These results reflect only a 5.9% absolute risk reduction in 5 years, which is just above 1% per year. Of note, improvement in outcome for patients randomized to undergo endarterectomy in this trial did not reach significance until 3 years after surgery. The European Asymptomatic Carotid Surgery Trial, the largest trial to date, largely replicated the results of ACAS, but in a somewhat more pragmatic setting.[152] This trial demonstrated that patients with asymptomatic carotid stenosis (≈70%) on ultrasound who were treated by immediate carotid endarterectomy plus medical treatment have a reduced 5-year risk for stroke compared with patients treated with medical therapy alone (6.4% vs. 11.8%). Of note, half of this 5-year benefit involved disabling or fatal strokes.

Although landmark randomized clinical trials have defined individuals who are likely to benefit from carotid endarterectomy (and set the standard for developing evidence-based practice guidelines throughout the world), it has been suggested that the significant increase in the number of carotid endarterectomies performed over the last decade may be due in part to the extrapolation of trial results to patients and settings not directly supported by the trials. For example, both NASCET and ACAS restricted enrollment to patients younger than 80 years of age, and both trials carefully selected institutions and surgeons to optimize the results of surgery. Additionally, subgroup analysis of ACAS could not demonstrate a significant benefit for women.[146] With the advent of a second interventional treatment modality, percutaneous carotid angioplasty and stenting (discussed later), and the evolution of intensive medical therapy, this issue has become more complex.

PERIOPERATIVE MORBIDITY AND MORTALITY

Although the randomized trials just noted have demonstrated a protective effect of carotid endarterectomy on ipsilateral stroke, the critical determinants of benefit for any given patient must include the overall perioperative event rate and expected long-term survival. Thus, the perioperative stroke and death rate for carotid endarterectomy needs to be very low to maintain the beneficial effects of surgery over medical therapy alone. Further, to compensate for the perioperative risk associated with surgery, the patient must have a reasonable life expectancy (12 to 18 months). The 30-day stroke and death rate of 2.3% for asymptomatic patients in ACAS (1987 to 1993) and 5.0% for symptomatic patients in NASCET (1988 to 1991) are often cited as benchmarks. More recent reports suggest a considerably less frequent event rate. For example, a prospective database study of 13,316 carotid endarterectomies performed in 2007 and 2008 reported a 30-day stroke and death rate of 1.3% in asymptomatic patients and 2.9% in symptomatic patients.[153] The 30-day mortality was significantly more frequent in patients who developed a stroke than in those who did not (12.9% vs. 0.6%). Patients with high-risk anatomy, such as restenosis and contralateral carotid arterial occlusion, have the highest risk for perioperative stroke and death. Neurologic deficits occur more commonly in patients with poorly controlled preoperative hypertension and in those with hypertension or hypotension postoperatively. The incidence of perioperative MI in patients undergoing carotid endarterectomy ranges from 0% to 5%. Recent reports suggest the incidence of MI is relatively low. The General Anesthesia versus Local Anesthesia for Carotid Surgery (GALA) trial (discussed later) results reported only 13 patients of 3526 (0.37%) had a perioperative MI.[154] The four fatal perioperative MIs accounted for only 8.9% of the total 30-day mortality. Although the role of carotid endarterectomy in patients older than 80 years of age remains a concern, recent reports suggest that carotid endarterectomy can be performed safely in the very elderly and those deemed high risk, with combined stroke or death rates being comparable to those found in randomized trials (NASCET and ACAS).

PREOPERATIVE ASSESSMENT

The optimal preoperative assessment for patients undergoing carotid endarterectomy continues to be debated (see also Chapter 31). Patients with recently symptomatic carotid disease present a particular challenge because strong evidence exists to support surgical intervention within 2 weeks after manifestation of symptoms, thus limiting the time available for evaluation and optimization of relevant comorbidities as well as the initiation of new medications.[155] The medical management of patients with asymptomatic carotid disease should be optimized and includes β-blockers, statins, and antiplatelet agents. Poorly controlled hypertension should be addressed with the patient's internist. The gradual decreasing of the arterial blood pressure over several weeks before surgery will restore intravascular volume, reset cerebral autoregulation to a more normal range, and improve perioperative management. Poorly controlled diabetes also warrants preoperative optimization, which may improve perioperative outcome.[156]

CAD is common in patients undergoing carotid endarterectomy and is a leading cause of both early and late mortality. Hertzer and co-workers[157] performed coronary angiograms in 506 patients scheduled for carotid endarterectomy and found significant (>70%) stenosis in one or more coronary artery, CAD in 83% of patients suspected of having CAD, and CAD in 40% thought to have no CAD. Despite the known frequent incidence of CAD in patients undergoing carotid endarterectomy, preoperative studies for the evaluation of myocardial function or ischemic potential are rarely undertaken. Exceptions to this practice are patients with unstable angina, recent MI with evidence of ongoing ischemia, decompensated congestive heart failure, and significant valvular disease. In general, specialized cardiac testing would be unlikely to result in cancellation of the procedure or alter perioperative management. Further, the relatively infrequent overall rates of perioperative nonfatal and fatal MI after carotid endarterectomy make aggressive strategies leading to prophylactic coronary revascularization less appealing.[154] A recent clinical trial reported on the safety and efficacy of coronary angiography and revascularization in preventing postoperative cardiac ischemic events after carotid endarterectomy. In a randomized fashion, 426 patients with no history of CAD were randomized to either coronary angiography before carotid endarterectomy (216 patients) or carotid endarterectomy without coronary angiography (210 patients). In the angiography group, 68 patients had a significant stenosis of the coronary arteries and underwent revascularization with PCI (66 patients) or CABG (2 patients). PCI was performed 1 to 8 days before surgery and always consisted of angioplasty and stenting. No patients in the angiography group had a postoperative cardiac ischemic event or complication related to PCI, whereas nine patients in the group without angiography had an ischemic event (one fatal MI and eight ischemic events treated medically). Although all PCI patients received dual-antiplatelet therapy, no major bleeding or neck hematomas were observed. Long-term follow-up was not reported.

Patients with combined carotid stenosis and CAD requiring coronary revascularization represent somewhat of a management dilemma because it is often unclear which disease should be treated first.[158] The severity of carotid and coronary disease must be evaluated in terms of clinical symptoms and anatomic lesions, and a decision must be made to perform a combined, staged (carotid endarterectomy first), or reverse-staged (CABG first) procedure. Carotid revascularization is recommended before CABG (staged procedure) in patients with symptomatic carotid disease and bilateral severe asymptomatic carotid stenosis. The optimal management of severe unilateral asymptomatic carotid stenosis in patients undergoing CABG is unclear. The only randomized clinical trial to date randomized 185 patients with severe unilateral asymptomatic carotid stenosis undergoing CABG to a staged or combined procedure (94 patients) or a reverse-staged procedure (90 patients).[159] Although the perioperative mortality rates were equivalent (~1.0%), the 90-day stroke and death rates were significantly lower in the staged and combined group (1.0% vs. 8.8%). Given the overall paucity of high-quality evidence, management of an individual patient should be guided by careful assessment of the relative severity of the coronary and carotid disease with particular emphasis on both surgeon-specific and institution-specific results in these patient populations. Carotid artery angioplasty and stenting is widely being applied as an alternative revascularization modality before staged CABG. More recently, a combined procedure (carotid angioplasty/stenting and CABG) has been introduced. In a small feasibility and safety study (90 patients), carotid artery angioplasty and stenting under local anesthesia followed immediately by CABG reported a 30-day stroke and death rate of 2.2%.[160]

ANESTHETIC MANAGEMENT

Anesthetic management goals for carotid endarterectomy include protection of the heart and brain from ischemic injury, control of the heart rate and arterial blood pressure, and ablation of the surgical pain and stress responses. These goals must be achieved with another important goal in mind—to have an awake patient at the end of surgery for the purpose of neurologic examination.

The preoperative visit is particularly important in patients undergoing carotid surgery. During this visit, a series of arterial blood pressure and heart rate measurements are obtained from which acceptable ranges for perioperative management can be determined. Patients are instructed to continue all long-term cardiac medications up to and including the morning of surgery. Aspirin therapy should be continued throughout the perioperative period. As noted earlier, discontinuation of aspirin therapy may be related to an increased rate of MI and transient ischemic events in patients undergoing carotid endarterectomy. When patients arrive at the hospital on the day of surgery, they are queried regarding any new cardiovascular or cerebrovascular symptoms. Long-term cardiovascular medications not taken at home should be administered in the preoperative holding area whenever possible. Patient reassurance is particularly important at this time because anxiety is associated with increases in heart rate, systemic vascular resistance, and myocardial O_2 consumption, which in this patient population could precipitate myocardial ischemia.

ECG monitoring should include continuous leads II and V_5 for detection of rhythm disturbances and ST-segment changes. An intraarterial catheter for beat-to-beat blood pressure monitoring should be considered routine. Noninvasive arterial blood pressure measurement in the contralateral arm is recommended. Central venous and pulmonary artery catheters are rarely indicated for carotid surgery. The rare patient with uncompensated heart failure or recent MI with ongoing ischemia requiring emergent surgery is a possible exception. If such monitors are used, the subclavian or femoral insertion sites are most practical because inadvertent carotid puncture could compromise blood flow as a result of hematoma. Oftentimes, the most common reason for central access is difficult or inadequate peripheral access. IV access for fluid and drug administration can be accomplished with two secure, medium-bore (16-gauge) peripheral IV catheters. Because both arms will be tucked to the patient's sides, the IV catheters must run well after patient positioning.

General Anesthesia

Any of the drugs commonly used to induce anesthesia, maintenance anesthetics, and nondepolarizing muscle relaxants can be used safely during carotid endarterectomy, given that stable hemodynamics are maintained and the patient is awake at the end of the procedure. A conventional technique is as follows. Sedative premedication (e.g., midazolam) has the potential to compromise early neurologic assessment and is universally avoided. After placement of routine monitors and administration of O_2 by facemask, small doses of opioid (e.g., fentanyl 0.5 to 1 μg/kg) are administered during arterial line placement. Induction of anesthesia is accomplished with incremental dosages of Propofol supplemented with additional opioid (total fentanyl dose 2 to 4 μg/kg). Etomidate also may be used and is preferred in patients with limited cardiac reserve. Neuromuscular relaxation with a short-acting to intermediate-acting nondepolarizing muscle relaxant such as rocuronium facilitates tracheal intubation. Esmolol is particularly effective in blunting the increases in heart rate and blood pressure responses during laryngoscopy and endotracheal intubation and is used liberally during the induction period. Arterial blood pressure responses during and after endotracheal intubation are unpredictable in this patient population, and the clinician must be prepared for immediate treatment of extremes in blood pressure. This can be achieved with the use of short-acting drugs, such as phenylephrine 50 to 100 μg for hypotension and sodium nitroprusside 5 to 25 μg or clevidipine 100 to 250 μg for hypertension. Patients with poorly controlled hypertension (diastolic blood pressure >100 mm Hg) require special care. These patients are often intravascularly volume depleted and may have significant hypotension with induction of anesthesia. Administration of fluids intravenously, careful titration of anesthetics, and immediate treatment of hypotension are especially important.

Anesthesia is maintained with inhaled volatile anesthetics. Sevoflurane or desflurane may be preferred because of more rapid emergence. Studies using EEG and regional cerebral blood flow (rCBF) measurements suggest that the critical rCBF (the rCBF below which EEG changes of cerebral ischemia occur) is lower for isoflurane. Sevoflurane's critical rCBF in patients undergoing endarterectomy is similar to that determined with isoflurane.[161,162] This use of 50%

N_2O in O_2 was previously favored; however, its use has been associated with increased post-operative nausea and vomiting. Maintenance anesthesia can also be achieved with a combination of inhaled volatile anesthetic in combination with propofol, remifentanil, or dexmedetomidine. If neuromonitoring is utilized, it would require inhaled volatile concentrations less than 0.5 minimum alveolar concentration (MAC) with supplementation of intravenous medications. Otherwise, clinical studies show no differences between volatiles and total intravenous anesthesia (TIVA).[163] With general anesthesia, a superficial plexus block is not required but can be considered as an adjunct.

Despite only modest surgical stimulation, hemodynamic fluctuations are common during carotid endarterectomy. Arterial blood pressure and heart rate are controlled within predetermined and individualized ranges during the surgical procedure with short-acting drugs whenever possible (phenylephrine, esmolol, nitroglycerin, sodium nitroprusside, nicardipine, clevidipine). Arterial blood pressure should be maintained in the high-normal range throughout the procedure and particularly during the period of carotid clamping to increase collateral flow and prevent cerebral ischemia. In patients with contralateral internal carotid artery occlusion or severe stenosis, induced hypertension to approximately 10% to 20% above baseline is advocated during the period of carotid clamping when neurophysiologic monitoring is not used. Arterial blood pressure preservation or augmentation can be accomplished by maintaining light levels of general anesthesia or by administering sympathomimetic drugs such as phenylephrine, ephedrine, or norepinephrine. Some caution must be exercised when using vasopressors to augment blood pressure during carotid endarterectomy because the increases in blood pressure and heart rate may increase myocardial ischemia[164] or infarction. The restrictive use of vasopressors for specific instances of cerebral ischemia has been advocated.[165] In one report, induced hypertension during the period of carotid occlusion was not associated with myocardial ischemia.[166]

Surgical manipulation of the carotid sinus with activation of the baroreceptor reflexes can cause abrupt bradycardia and hypotension. Cessation of surgical manipulation promptly restores the hemodynamics, and infiltration of the carotid bifurcation with 1% lidocaine usually prevents further episodes. Infiltration may, however, increase the incidence of both intraoperative and postoperative hypertension.[167]

On application of the surgical dressings, drugs used to reverse neuromuscular blockade (i.e., neostigmine or sugammadex) are administered and O_2 is increased to 100%. Ventilation is gently assisted until the patient exhibits spontaneously eye opening or movement. With rare exceptions, all tracheas are extubated after neurologic integrity is established. Neurologic deficits on emergence require immediate discussion with the surgeon about the need for angiography, reoperation, or both. The period of emergence and extubation may be associated with marked hypertension and tachycardia, which may require aggressive pharmacologic intervention. Tight hemodynamic control during this period is likely to be more demanding than during induction. Greater hemodynamic stability and decreased pharmacologic intervention during emergence have been reported in patients undergoing carotid endarterectomy with propofol versus isoflurane. In addition, a significantly less frequent incidence of myocardial ischemia on emergence was found in the propofol group than in the isoflurane group (1 of 14 vs. 6 of 13). Of particular note, all patients with myocardial ischemia on emergence had systolic blood pressure higher than 200 mm Hg.

Regional and Local Anesthesia

Regional and local anesthetic techniques for carotid endarterectomy have been in use for more than 50 years, and many centers consider them to be the techniques of choice. Regional anesthesia is accomplished by blocking the C2 to C4 dermatomes by use of a superficial, intermediate, deep, or combined cervical plexus block (see also Chapter 46). Adequate anesthesia can be obtained with an isolated superficial or intermediate cervical plexus block, likely as a result of spread of local anesthetic to the cervical nerve roots.[168] Local infiltration of the incisional site and surgical field can also provide the necessary sensory blockade. A recent systematic review including over 10,000 cervical plexus blocks for carotid endarterectomy found that the deep (or combined) block was associated with a higher serious complication rate related to the injecting needle compared with a superficial (or intermediate) block (0.25% vs. 0%).[169] The conversion rate to general anesthesia was also higher with the deep block (2.1% vs. 0.4%). No difference was found in the incidence of serious systemic complications between the blocks. Although the incidence of serious complications from a cervical plexus block is infrequent, near-toxic levels of local anesthetic occurs in almost half of patients after superficial and deep cervical plexus block.[170] Although no major complications related to local anesthetic toxicity occurred, some caution should be exercised when requesting the surgeon to supplement with additional local anesthetic.

Regional and local anesthesia allows continuous neurologic assessment of the awake patient, which is widely considered to be the most sensitive method for detecting inadequate cerebral perfusion and function. Awake monitoring reduces the need for shunting and avoids the expense associated with indirect monitors of cerebral perfusion. Other advantages that have been reported include greater stability of blood pressure and decreased vasopressor requirements, reduced operative site bleeding, and reduced hospital costs. Potential disadvantages of local or regional anesthesia include an inability to use pharmacologic cerebral protection with anesthetics, patient panic or loss of cooperation, seizure or loss of consciousness with carotid clamping, and inadequate access to the airway should conversion to general anesthesia be necessary. The reported incidence of intraoperative neurologic changes during carotid endarterectomy under local or regional anesthesia varies widely (2.4% to 24%). Rates of conversion from regional anesthesia to general anesthesia of approximately 2% to 6% have been reported. Phrenic nerve paresis is common after cervical plexus block and is of little clinical consequence except in patients with severe COPD or contralateral diaphragmatic dysfunction.

Regional and local anesthesia requires significant patient cooperation throughout the procedure and is best maintained with constant communication and gentle handling of tissues. Supplemental infiltration of local anesthetic by the surgeon, especially at the lower border and ramus of the mandible, is frequently helpful. Sedation, if used at all, must be kept to a minimum to allow continuous neurologic assessment. The surgical drapes are "tented" over the head and face area to minimize claustrophobic anxiety. Levels of consciousness, speech, and contralateral handgrip are assessed throughout the procedure. If both arms are tucked to the patient's sides, handgrip can be assessed with the use of a squeaky toy. Blood pressure is augmented with phenylephrine when patients exhibit neurologic changes during carotid artery test clamping or after shunt placement. A 2- to 3-minute test clamp in awake patients allows prompt identification of those who would benefit from shunt placement. Patient acceptance of regional anesthesia is frequent and common, as evidenced by a 92% preference for repeat cervical plexus block for future carotid endarterectomy. Regional anesthesia should be avoided under the following circumstances: strong preference for general anesthesia expressed by the patient (i.e., claustrophobia), language barriers that make communication difficult, and difficult vascular anatomy. Difficult anatomy is usually manifested by a patient with a short neck and a high (more cephalad) bifurcation and may require vigorous submandibular surgical retraction.

Regional Versus General Anesthesia

For decades, the impact of anesthetic technique on outcome for carotid endarterectomy has been debated and studied. Until recently, nonrandomized studies dominated and largely supported that regional anesthesia was associated with significant reductions in the risk for perioperative death, stroke, MI, and pulmonary complications.[171] The lack of randomized data was addressed with the landmark GALA trial.[154] This multicenter, randomized controlled trial included 3526 patients with symptomatic or asymptomatic internal carotid stenosis from 95 medical centers in 24 countries. Patients were randomly assigned to carotid endarterectomy under general anesthesia (1753 patients) or local anesthesia (1773 patients) between 1999 and 2007. The primary outcome was a composite of perioperative death, MI, and stroke (including retinal infarction). The main finding was that anesthetic technique was not associated with a significant difference in the composite end point (4.8% for general vs. 4.5% for local). Anesthetic technique was not associated with a significant difference in secondary outcomes, including duration of surgery, duration of ICU stay, length of hospital stay, or quality of life at 1 month after surgery. Other outcomes, including cranial nerve injury (10.5% vs. 12.0%), wound hematoma (8.3% vs. 8.5%), wound hematoma requiring reoperation (2.6% vs. 2.3%), and chest infection (2.0% vs. 1.9%) were similar between patients receiving general anesthesia and local anesthesia, respectively. Of note, 4.4% of patients under local anesthesia (93% received a cervical plexus block) had complications that lead to cancellation of surgery or conversion to general anesthesia. Important limitations of the GALA trial include lack of standardization, absence of blinding, and possible investigator bias. Using patient-level data from the GALA trial, a recent report found that local anesthesia had a cost-effectiveness benefit over general anesthesia.[172]

Although randomized clinical trials such as GALA are considered to be the gold standard in clinical research, the conclusions are not always generalizable and therefore may not reflect actual practice in treating unselected patients. A recent report from a large international vascular registry, including 20,141 carotid endarterectomies performed in 10 countries between 2003 and 2007, found that anesthetic technique had no effect on perioperative mortality (0.5% overall) or stroke rate (1.5% overall).[173] These real-world results complement the data from the GALA trial. Thus, using major perioperative complications as a guide, there is no reason to routinely prefer one anesthetic technique over the other for carotid endarterectomy. The ultimate decision to use general anesthesia or regional anesthesia should be based on surgeon and the anesthesiologist experience and patient preference.

Carbon Dioxide and Glucose Management

Cerebrovascular CO_2 reactivity is part of the complex autoregulatory system to control cerebral blood flow. Normal cerebral autoregulation responds to acute changes in $PaCO_2$ by decreasing cerebral blood flow (i.e., vasoconstriction) with hypocapnia and increasing cerebral blood flow (i.e., vasodilatation) with hypercapnia. In patients with carotid artery stenosis or occlusion, ipsilateral cerebral blood flow may be impaired because of poor intracerebral collateral blood flow. In the setting of poor collateralization and resultant cerebral hypoperfusion, cerebral resistance vessels in the hypoperfused territories will dilate to maintain cerebral blood flow. These chronically dilated resistance vessels may demonstrate a diminished or absent (i.e., vasomotor paralysis) cerebral blood flow response to CO_2. Impaired cerebrovascular reactivity to hypercapnia may play a role in the development of stroke ipsilateral to carotid stenosis or occlusion. Although one might expect that impaired CO_2 reactivity would increase the risk for cerebral ischemia after carotid artery clamping, the results of intraoperative cerebral monitoring suggest that no such relationship exists. Impaired cerebrovascular reactivity to CO_2 will significantly improve after carotid endarterectomy.

Control of ventilation and end-tidal CO_2 ($ETCO_2$) during general anesthesia is a matter of some controversy. Hypercapnia may cause a "steal" phenomenon (i.e., shunting of blood away from hypoperfused territories with dilated vasculature) and is generally avoided. Hypocapnia, with its associated cerebral vasoconstriction, has been advocated to promote a reversal of this steal phenomenon. However, little clinical evidence exists for this "reverse" steal effect. Additionally, experimental data do not support the use of hypocapnia as a therapeutic maneuver to produce a favorable redistribution of blood flow during focal cerebral ischemia. Indeed, in this animal model of focal cerebral ischemia, hypocapnia ($PaCO_2$ of 23 mm Hg) actually increased the size of the region at risk for ischemia. It is therefore common practice to maintain normocapnia or mild hypocapnia during carotid endarterectomy.

Evidence demonstrates increased ischemic injury to neural tissue when ischemia occurs in the presence of hyperglycemia. Data from The Johns Hopkins Hospital found that operative-day glucose greater than 200 mg/dL at the time of carotid endarterectomy was associated with an increased risk for perioperative stroke or transient ischemic attack, MI, and death.[156] Thus, until additional data become available, it may be beneficial to maintain a blood glucose level below 200 mg/dL in patients undergoing carotid endarterectomy. If hyperglycemia is treated with insulin preoperatively or intraoperatively, the blood glucose level should be carefully monitored, especially during general anesthesia, to avoid the dangers of hypoglycemia.

NEUROLOGIC MONITORING AND CEREBRAL PERFUSION

Intraoperative monitoring for cerebral ischemia or hypoperfusion and, more recently, for cerebral emboli during carotid endarterectomy is controversial (see also Chapter 39). Monitoring techniques include internal carotid artery stump pressure determinations, rCBF measurements, EEG monitoring, SSEP monitoring, transcranial Doppler ultrasonography (TCD), and cerebral oximetry monitoring. The rationale for the use of such monitoring is based on the need to prevent intraoperative strokes. The primary clinical utility of cerebral monitoring is to identify patients who may benefit from shunting during the period of arterial clamping. Secondarily, cerebral monitoring is used to identify patients who may benefit from blood pressure augmentation or change in surgical technique. Despite a tremendous amount of investigative effort, only limited data support the assumption that cerebral monitoring actually improves patient outcome after carotid endarterectomy. To further complicate the issue, several large series have reported excellent results from carotid endarterectomy with routine shunting, routine no shunting, and selective shunting using one or more of the methods discussed later. In a review, the mean reported stroke rate with routine shunting was 1.4% and for routine no shunting was 2%.[174] The mean perioperative stroke rates for selective shunting were 1.6% using stump pressure, 1.6% using EEG, 1.8% using SSEP, and 4.8% using TCD.[174]

Carotid Artery Stump Pressure

The internal carotid artery stump pressure represents the back-pressure resulting from collateral flow through the circle of Willis via the contralateral carotid artery and the vertebrobasilar system. The advantages of monitoring carotid stump pressure are that it is inexpensive, relatively easy to obtain, and continuously available during carotid clamping (dynamic stump pressure). Despite these advantages, few centers use stump pressure monitoring. A recent single center report of 1135 consecutive carotid endarterectomies under general anesthesia used a stump pressure of below 45 mm Hg as a guide for selective shunting.[175] The 30-day stroke rate was 3% for patients selectively shunted (21%), 0.5% for patients not shunted (79%), and 1% overall. The overall 30-day mortality was 0.5%. Of note, no patient had a stroke caused by global intraoperative cerebral hypoperfusion. A recent prospective randomized trial comparing routine shunting versus selective shunting based on stump pressure below 40 mm Hg in 200 patients undergoing carotid endarterectomy under general anesthesia found both methods were associated with an infrequent perioperative stroke rate (0% vs. 2%).[176] The two strokes in the selective shunting cohort were related to carotid artery thrombosis. No patients died perioperatively. Although an old method, stump pressure monitoring appears to have survived the test of time.

Regional Cerebral Blood Flow

rCBF measurements during carotid endarterectomy are obtained by IV or ipsilateral carotid artery injection of radioactive xenon and analysis of decay curves obtained from detectors placed over the area of the ipsilateral cortex supplied by the middle cerebral artery. Measurements are typically obtained before, during, and immediately after carotid clamping. This technology, combined with the EEG monitoring, has provided important insight into the relationship between rCBF and EEG evidence of cerebral ischemia and the critical rCBF associated with various anesthetics.[177,178] The critical rCBF varies depending on the volatile anesthetic used. In patients receiving N_2O plus a volatile anesthetic, rCBF is approximately 20, 15, 10, and 10 mL/100 g of brain tissue per minute for halothane, enflurane, isoflurane, and sevoflurane, respectively.[161,177,178] The expense and the expertise required to make and interpret these blood flow measurements have limited the use of this technology to only a few centers.

Electroencephalography

Many centers advocate intraoperative use of EEG monitoring for the detection of cerebral ischemia and subsequent selective shunting (see also Chapter 39). The full 16-channel strip-chart EEG and the processed (compressed spectral array) EEG monitor are used for this purpose. Although the processed EEG monitor is more easily interpreted, it is less sensitive than the raw EEG monitor. Significant ischemic EEG changes occur in 7.5% to 20% of monitored patients during carotid clamping under general anesthesia. Significant EEG changes occur more frequently in patients with contralateral carotid disease than in those without (14.3% vs. 5.1%). The presence of a contralateral carotid occlusion may increase the rate of significant ischemic EEG changes to nearly 50% during carotid clamping. Because contralateral occlusion is highly predictive of ischemic EEG changes with carotid clamping, it has been recommended that EEG monitoring be eliminated in this circumstance. Ischemic EEG changes may also be seen with shunt malfunction, hypotension, or cerebral emboli.

When the electroencephalogram is used for cerebral ischemia monitoring during carotid endarterectomy, a stable physiologic and anesthetic milieu is mandatory. Isoflurane, desflurane, and sevoflurane produce similar ECG changes at equipotent levels and, when used at 0.5 MAC, allow for reliable ECG cerebral ischemia monitoring.

The clinical usefulness of intraoperative EEG monitoring for ischemia during carotid endarterectomy is limited by several factors. First, it may not detect subcortical or small cortical infarcts. Second, false-negative results (i.e., neurologic deficit with no ischemic EEG changes intraoperatively) are common. Patients with preexisting stroke or reversible neurologic deficits may have a particularly high incidence of such results. Third, EEG monitoring is not specific for ischemia and may be affected by changes in temperature, blood pressure, and anesthesia depth. Fourth, false-positive results (i.e., no perioperative neurologic deficit with significant ischemic EEG changes intraoperatively) occur because not all cerebral ischemia uniformly proceeds to infarction. Finally, intraoperative EEG monitoring is inherently limited because most intraoperative strokes are thought to be thromboembolic and most perioperative strokes occur postoperatively. At present, no consistent data demonstrate that EEG monitoring is clearly superior to other methods of intraoperative cerebral monitoring or that the use of EEG monitoring improves outcome.

Somatosensory Evoked Potentials

SSEP monitoring is based on the response of the sensory cortex to electrical impulses from peripheral sensory nerve stimulation. The sensory cortex, being primarily supplied by the middle cerebral artery, is at risk during carotid artery clamping. SSEP monitoring, unlike EEG monitoring, can detect subcortical sensory pathway ischemia. Characteristic SSEP tracings (i.e., decrease in amplitude, increase in latency, or both) occur with decreased rCBF and are abolished in primates when flow decreases to less than 12 mL/100 g of brain tissue per minute. No specific reduction in amplitude or increase in latency has been established as a physiologic marker of impaired rCBF under operative conditions in humans. Anesthetics, hypothermia, and blood pressure may affect SSEPs significantly, and false-negative results have been reported. The validity of SSEPs as an intraoperative monitor of cerebral ischemia during carotid endarterectomy has not been definitively established.

Transcranial Doppler Ultrasonography

TCD allows continuous measurement of mean blood flow velocity and detection of microembolic events in the middle cerebral artery (see also Chapter 39). These parameters have important clinical implications because most perioperative neurologic deficits are thought to be thromboembolic in origin. With TCD, intraoperative embolization has been detected in more than 90% of patients undergoing carotid endarterectomy. Most intraoperative emboli are characteristic of air and are not associated with adverse neurologic outcomes. TCD may provide useful information regarding shunt function, malfunction, and the incidence of emboli during shunt insertion. Embolization during carotid artery dissection may indicate plaque instability and the need for early carotid artery clamping. Embolization during dissection and wound closure is associated with operative stroke. One center has reported that combined TCD monitoring and completion angiography resulted in a reduction in the intraoperative stroke rate from 4% to 0%. Early postoperative embolization has been detected in more than 70% of patients after carotid endarterectomy and is exclusively particulate in nature. Most TCD-detected emboli occur in the first 2 to 3 hours after surgery. Persistent particulate embolization in the early postoperative period has been shown to predict thrombosis and the development of a major neurologic deficit. Frequent early postoperative TCD embolic signals have been demonstrated to be highly predictive of early postoperative ipsilateral focal cerebral ischemia. Intervention with dextran has been shown to reduce and ultimately stop sustained embolization after carotid endarterectomy. Perioperative microembolization is more common in women and patients with symptomatic carotid disease. TCD monitoring has been reported to detect early asymptomatic carotid artery occlusion and hyperperfusion syndrome after carotid endarterectomy. Although TCD monitoring holds some promise, conclusive evidence demonstrating improved outcome has not been reported. Additionally, the high rate of technical failures significantly limits the clinical utility of this monitoring modality.[179]

Cerebral Oxygenation

Direct monitoring of cerebral oxygenation can be obtained with jugular bulb venous monitoring. Such monitoring allows determination of the arterial-jugular venous O_2 content difference and jugular venous O_2 saturation and therefore provides information on global cerebral O_2 metabolism. Jugular venous samples are obtained from a catheter inserted into the jugular bulb ipsilateral to the surgical site. Continuous fiberoptic jugular venous oximetry catheters are available as well. Significant technical and methodologic shortcomings have limited the clinical application of this monitoring during carotid endarterectomy.

Near-infrared spectrophotometry is a noninvasive technique that allows continuous monitoring of regional cerebral O_2 saturation through the scalp and skull. Similar to pulse oximetry, cerebral oximetry is based on the different absorption characteristics of the near-infrared spectrum of oxygenated and deoxygenated hemoglobin. However, unlike pulse oximeters, cerebral oximeters measure the O_2 saturation of hemoglobin in the entire tissue bed (i.e., brain tissue and arterial and venous blood), which is predominately venous blood, and therefore approximates venous blood O_2 saturation. A commercially available cerebral oximetry sensor is applied to the forehead skin ipsilateral to the surgical site, and regional cerebral O_2 saturation from a small sample of the frontal cortex below the sensor is provided. To date, wide patient-to-patient variability in baseline cerebral O_2 saturation and the lack of a clinical threshold of a decrease in cerebral O_2 saturation predictive of the need for shunt placement have impeded the widespread use of this novel monitoring modality.

POSTOPERATIVE CONSIDERATIONS

Most neurologic complications (transient and permanent) after carotid endarterectomy are explained by intraoperative embolization, hypoperfusion during carotid clamping, and postoperative embolization or thrombosis from the endarterectomy site. It is generally accepted that most neurologic complications are related to surgical technique. Thromboembolic (rather than hemodynamic) factors appear to be the major mechanism of perioperative neurologic complications and most occur in the postoperative period. Neurologic complications attributable to carotid artery thrombosis may occur with an incidence as frequent as 3.3% and are associated with a high rate of major stroke or death despite immediate operative intervention. Other important, but less common neurologic complications include intracerebral hemorrhage and cerebral hyperperfusion. The reported incidence of intracerebral hemorrhage after carotid endarterectomy ranges from 0.4% to 2.0%. Most intracerebral hemorrhages occur 1 to 5 days after the operation and are associated with significant morbidity and mortality.

Hypertension is common in the postoperative period after carotid endarterectomy. Not surprisingly, patients with poorly controlled preoperative hypertension often have severe hypertension postoperatively. The causes are not well understood, but surgical denervation of the carotid sinus baroreceptors is probably contributory. Regional anesthesia is associated with less hypertension. Other causes of postoperative hypertension, such as hypoxemia, hypercapnia, bladder distention, and pain, should be excluded or treated. Because neurologic and cardiac complications may be associated with postoperative hypertension, blood pressure should be aggressively controlled to near preoperative values after surgery. Short-acting drugs are the safest and most effective. Patients with persistent hypertension can be converted to longer-acting IV or oral agents before discharge from the ICU.

Postoperative cerebral hyperperfusion syndrome is an abrupt increase in blood flow with loss of autoregulation in the surgically reperfused brain and is manifested as headache, seizure, focal neurologic signs, brain edema, and possibly intracerebral hemorrhage. Unfortunately, little is actually known about the cause and management of this syndrome. Typically, this syndrome does not occur until several days after carotid endarterectomy. Patients with severe postoperative hypertension and severe preoperative internal carotid artery stenosis are believed to be at increased risk for this syndrome. However, more recent data do not corroborate this common belief and suggest that recent contralateral carotid endarterectomy may be predictive of cerebral hyperperfusion.[180]

Postoperative hypotension occurs almost as frequently as hypertension after carotid endarterectomy. Carotid sinus baroreceptor hypersensitivity or reactivation probably plays an important role. Postoperative hypotension may be more common after regional anesthesia. To avoid cerebral and myocardial ischemia, hypotension should be corrected promptly. Cardiac output is frequently normal or elevated and systemic vascular resistance reduced in hypotensive patients after carotid endarterectomy. Intensive surveillance for evidence of myocardial and cerebral ischemia and judicious use of fluids and vasopressors are recommended for postoperative hypotension. In most cases, the hypotension resolves over a period of 12 to 24 hours.

Cranial and cervical nerve dysfunction after carotid endarterectomy is well documented in the literature. Although most injuries are transient, permanent injuries can lead to significant disability. Patients should be examined for injury to the recurrent laryngeal, superior laryngeal, hypoglossal, and marginal mandibular nerves shortly after extubation. Unilateral recurrent laryngeal nerve injury may result in ipsilateral true vocal cord paralysis in the paramedian position. Although most patients have hoarseness and an impaired cough mechanism, the injury is usually well tolerated. However, bilateral recurrent laryngeal nerve injury and resultant bilateral vocal cord paralysis can result in life-threatening upper airway obstruction. This situation must be anticipated in patients who have previously undergone contralateral carotid endarterectomy or neck surgery.

Carotid body denervation may occur after carotid endarterectomy as a result of surgical manipulation. Unilateral loss of carotid body function may result in an impaired ventilatory response to mild hypoxemia and is rarely of clinical significance. Bilateral carotid endarterectomy is associated with loss of the normal ventilatory and arterial pressure responses to acute hypoxia and an increased resting partial pressure of arterial CO_2. In this situation, the central chemoreceptors are the primary sensors for maintaining ventilation, and serious respiratory depression may result from opioid administration. Fortunately, most patients require little more than acetaminophen or ketorolac for postoperative pain.

Wound hematoma probably occurs more frequently than reported in the literature. In the NASCET,[145] 5.5% of patients had wound hematomas. Most cases are the result of venous oozing and require little more than external compression for 5 to 10 minutes. Expanding hematomas require prompt evaluation at the bedside and immediate evacuation if airway compromise is evident. Aggressive postoperative blood pressure control may help reduce the incidence of hematoma.

Although some clinicians believe that intensive care monitoring is not routinely required after carotid surgery, a significant number of patients do require intensive monitoring and active intervention. I think all patients should be monitored in an intensive care setting for at least 8 hours after carotid endarterectomy, because most events requiring intervention occur within this timeframe.[181,182]

Endovascular Treatment of Carotid Disease: Carotid Artery Stenting

Endovascular treatment of carotid disease is an innovation in evolution for stroke prevention and currently involves percutaneous transluminal angioplasty and stenting. Significant procedural advancements include the use of dual antiplatelet therapy, self-expanding stents, and emboli protection devices. Over the last decade, major randomized clinical trials comparing carotid endarterectomy with carotid artery stenting have been published. A recent systematic review of randomized trials (16 trials involving 7572 patients) found that endovascular treatment (including balloon angioplasty or stenting) was associated with an increased risk for periprocedural stroke or death compared with endarterectomy.[183] Of note, the increase in risk appeared to be limited to patients 70 years of age and older. Endovascular treatment was associated with lower risks for MI, cranial nerve palsy, and access site hematomas. The rate of ipsilateral stroke after the periprocedural period was not different between treatment groups. Among patients unfit for surgery, the rate of death or stroke did not differ between endovascular treatment and medical care. Updated guidelines provide specific recommendations for revascularization of symptomatic and asymptomatic patients.[149]

The carotid artery stenting procedure consists of the following steps: femoral access, aortic arch angiogram, selective cannulation of the common carotid artery origin and angiogram, guidewire advancement into the external carotid artery, carotid sheath placement and advancement into the common carotid artery, placement of embolic protection device, balloon angioplasty of lesion, advancement of stent delivery catheter across dilated lesion, deployment of self-expanding stent, balloon dilation of stent, completion angiogram, and access site management. The femoral artery approach is considered standard, but brachial artery and high radial artery access have been reported with high procedural success. Embolic protection devices are considered mandatory and include distal protection in the form of a filter or occlusion balloon and proximal protection in the form of flow interruption or flow reversal. Cardiologists and radiologists currently perform a large percentage of these procedures in specialized endovascular suites.

Most carotid artery stenting procedures are performed under local anesthesia with light or no sedation to facilitate patient cooperation and continuous neurologic assessment. In addition to routine monitors, an arterial line is placed for continuous blood pressure monitoring. Some degree of hemodynamic instability is common in patients during and after carotid artery stenting. Bradycardia and hypotension occur much more frequently after carotid artery stenting with balloon angioplasty than without angioplasty.[184] A recent, large retrospective study reported asystole in 4.9% of patients after carotid stenting.[185] Asystole was more likely to occur in patients undergoing a right-sided procedure, in those with significant contralateral stenosis, and in those with a reduced left ventricular ejection fraction. The administration of prophylactic atropine before balloon inflation decreases the incidence of intraoperative bradycardia and cardiac morbidity in primary carotid stenting patients.[186]

Lower Extremity Revascularization

PERIPHERAL ARTERY DISEASE

The peripheral artery disease (PAD) or atherosclerotic occlusive disease of lower extremities is one of the resources-consuming diseases in the United States health care system.[187] The key risk associated with PAD is the amputation of lower extremity, and this disease also accounts for atherosclerosis in the renovascular, cerebrovascular, cardiovascular beds. These are the reasons the PAD patient is vulnerable to stroke, myocardial infraction (MI), and even death.[188] Studies also show that diabetic patients are at high risk of developing significant long-term disability.[189] Owing to these facts, Hirsch et al. highlighted that the PAD patients undergo expensive treatment due to a broad range of therapeutic procedures and diagnostic tests involved.[190]

PERIOPERATIVE MANAGEMENT OF ANTIPLATELETS AND ANTICOAGULANT IN PAD PATIENTS

The long-term management of PAD patients includes an increasing use of effective antiplatelet and anticoagulant medications wherein managing these medications during the perioperative period becomes challenging due to the various risks and benefits.[191] The increased risk of bleeding is one of the major concerns associated with perioperative management and if the antiplatelet therapy is paused, the patients are at higher risk of thrombotic complications due to the surgery-related prothrombotic effects.[192]

Single Antiplatelet Therapy in Symptomatic Peripheral Artery Disease

According to Trialists Collaboration, the PAD patients showed 23% reduction in critical vascular events when they performed 42 randomized clinical trials and conducted a meta-analysis of 9214 patients who were prescribed single antiplatelet therapy (SAPT).[193] Another important study conducted by Mahmoud and associates includes an investigation regarding the efficacy of aspirin in both asymptomatic and symptomatic patients with peripheral vascular disease and they concluded that neither the worse bleeding outcomes nor the improved cardiovascular results were strictly associated with the use of aspirin.[194] They concluded that there is a great need to conduct large-scale randomized trials to confirm the efficacy of aspirin in these conditions.

Dual Antiplatelet Therapy in Symptomatic Peripheral Artery Disease

Field and Benavenate highlighted the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance (CHARISMA) study wherein they compared the aspirin alone with aspirin plus clopidogrel with (75 to 162 mg/d) and (75 mg/d) in 15,603 patients who were affected with asymptomatic multiple vascular risk factors and with symptomatic vascular disease.[195] The results revealed no noticeable difference in both patients' groups, and as a matter of fact, an increased bleeding risk was shown in the patients.

Another study, the PEGASUS-TIMI 54 trial, "Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin-Thrombolysis in Myocardial Infarction" was conducted by Bonaca and associates, in which they studied the use of ticagrelor (a reversible P2Y12 inhibitor) in the patients with prior history of heart attack and the findings suggested that ticagrelor significantly reduced the risk of cardiovascular death, myocardial infarction, and strokes at the expense of an increased risk of major bleeding.[196]

The Rivaroxaban for the Prevention of Major Cardiovascular Events in Coronary or Peripheral Artery Disease (COM-PASS) trial randomly assigned 27,395 participants with stable atherosclerotic vascular disease to receive rivaroxaban (a direct factor Xa inhibitor) (2.5 mg twice a day) plus aspirin (100 mg daily), rivaroxaban alone (5 mg twice a day), or aspirin alone (100 mg daily).[197] The primary outcome was a composite of cardiovascular death, stroke, or myocardial infarction. The trial was stopped because of an overwhelming efficacy. Total mortality, CAD mortality, and cardiovascular mortality were lowered by 20%. The COM-PASS trial provided a strong evidence for an alternative to clopidogrel when it comes to patients who are pharmacogenetically resistant to it (slow responders) due to genetic variations in the CYP2C19 enzyme responsible for its activation in the liver. It is assumed that 30% of patients may be pharmacogenetically resistant to clopidogrel.

OPEN BYPASS SURGERIES AND ANESTHESIA MANAGEMENT

Generally, the open bypass surgery and the endovascular revascularization are the two options to operate on PAD patients,[198] particularly when the patient doesn't show improvement after medical therapy and also those patients who are affected with critical limb ischemia.[199,200] In this regard, due to the presence of significant comorbidities in these patients, the patients are at risk for major perioperative complications. While general anesthesia is usually used for open peripheral revascularization surgeries, regional and neuraxial anesthesia could also be employed.[201] They could add the advantage of postoperative pain control and improved perioperative hemodynamic stability. The ASRA guidelines for antithrombotic should be considered before performing neuraxial or regional anesthesia, especially because moderate doses of heparin are used in distal bypass surgeries during arterial clamping.[155]

ENDOVASCULAR TREATMENT OF PERIPHERAL ARTERIAL DISEASE

General anesthesia, neuraxial anesthesia, or MAC can be used for peripheral arterial stenting procedures since they are usually done through percutaneous punctures. We often use MAC unless there are other indications for different techniques. Like any other percutaneous intervention, the same indications and contraindications apply such as patient consent to awake or conscious sedation, patient's ability to lie flat for femoral access, and lying still for the duration of the procedure. What is different in those cases is that the percutaneous access could be affected by the disease process, for example, common femoral stenosis, which may need an open cutdown or even a combined common femoral endarterectomy before stenting the distal arteries. If this is the cases the choices for anesthesia will be limited to either general anesthesia or neuraxial anesthesia. Again, ASRA guidelines should be respected if neuraxial anesthesia is considered.[155] It should be noted that several research studies underline the fact that there is no noticeable difference among patients who receive either general anesthesia or neuraxial block in terms of cardiac outcomes.[8,9]

Anesthesia for Neurologic Surgery and Neurointerventions

BRIAN P. LEMKUIL, JOHN C. DRUMMOND, PIYUSH M. PATEL, and
ARTHUR LAM

KEY POINTS

- For the purposes of planning a strategy for controlling intracranial pressure (ICP), the four subcompartments of the intracranial space should be considered: cells, interstitial and intracellular fluid, cerebrospinal fluid (CSF), and blood.
- The clinician should make a preoperative assessment of the probable intracranial compliance reserve as the basis for selection of appropriate anesthetic drugs and techniques.
- The venous side of the cerebral circulation is a largely passive compartment that is often the cause of increased ICP, or "tightness," of the surgical field.
- Cerebral perfusion pressure (CPP) should be supported at or near normal waking levels in patients with recent cerebral injuries (e.g., traumatic brain injury [TBI], subarachnoid hemorrhage [SAH], and spinal cord injury [SCI]) because of low resting cerebral blood flow and impaired autoregulation.
- When neurosurgical procedures are performed in the sitting position, blood pressure should be corrected to the level of the external auditory meatus and mean arterial pressure (MAP) should be maintained at 60 mm Hg in normotensive adults.
- Monitoring for venous air embolism (VAE) in at-risk situations includes the precordial Doppler and end-tidal carbon dioxide analysis.
- Despite encouraging preclinical data, therapeutic mild hypothermia cannot be advocated in the care of head-injured patients in the intensive care unit (ICU) or during the operative management of patients with intracranial aneurysms because of negative human trial results for those patient groups.
- The most important consideration in the anesthetic management of patients undergoing clipping or coiling after acute SAH is the prevention of paroxysmal hypertension with its attendant risk of aneurysm rerupture. Nonetheless, adequate perfusion pressure is needed if temporary clips are used during management of a cerebral aneurysm.
- Although induced hypotension is rarely used electively in aneurysm surgery, the clinician must be ready to reduce blood pressure immediately and accurately in the event of aneurysm rupture.
- Tracheal intubation of a head-injured patient with an undefined cervical spine injury can be accomplished using rapid sequence induction with manual in-line stabilization (the occiput held rigidly to the backboard), with only a very small risk of injury to the spinal cord.
- CPP (CPP = MAP - ICP) should be supported to a target range of 60 to 70 mm Hg in the first 48 to 72 hours after TBI in adults.
- Hypocapnia has the potential to cause cerebral ischemia, particularly in a recently injured brain and in a brain beneath retractors; it should be used only when absolutely necessary for the control of critically increased or uncertain ICP.

This chapter provides guidelines for the management of common situations in neurosurgical anesthesia. Issues that arise in connection with a wide variety of neurosurgical procedures—those constituting a checklist that the practitioner should review before undertaking anesthesia for any neurosurgical procedure—are reviewed first, followed by procedure-specific discussions. This chapter assumes familiarity with the cerebral physiology and effects of anesthetics as described in Chapter 11, and with neurologic monitoring as described in Chapter 39. Carotid endarterectomy (CEA) and carotid angioplasty and stenting are discussed in Chapter 56.

Recurrent Issues in Neuroanesthesia

Several basic elements of neurosurgical and neuroanesthetic management are recurrent and, in the absence of an established understanding between surgeon and anesthesiologist, should be discussed and agreed upon at the outset of every neurosurgical procedure (Box 57.1). The list varies by procedure and may include the intended surgical position and requisite positioning aids; intentions with respect to the use of steroids, osmotic agents/diuretics, anticonvulsants, and antibiotics; the surgeon's perception of the "tightness" of the intracranial space and the remaining intracranial compliance reserve; appropriate objectives for the management of blood pressure, carbon dioxide tension, and body temperature; anticipated blood loss; the intended use of neurophysiologic monitoring (which may impose constraints on the use of anesthetics or muscle relaxants, or both); and, sometimes, the perceived risk of air embolism. The considerations driving the decisions made about these issues are presented in this section. One additional recurrent issue, brain protection, is discussed briefly in the section on aneurysms and arteriovenous malformations (AVMs) and in detail in Chapter 11.

BOX 57.1 **Recurrent Issues in Neuroanesthesia**

- Control of intracranial pressure/brain relaxation
- Management of $PaCO_2$
- Management of arterial blood pressure
- Use of steroids
- Use of osmotherapy
- Use of diuretics
- Use of anticonvulsants
- Patient positioning
- Pneumocephalus
- Venous air embolism
- Monitoring
- Intravenous fluid management
- Hypothermia
- Glucose management
- Emergence from anesthesia

CONTROL OF INTRACRANIAL PRESSURE AND BRAIN RELAXATION

The necessity of preventing increases in intracranial pressure (ICP) or reducing ICP that is already increased is recurrent in neuroanesthesia. When the cranium is closed, the objectives are to maintain adequate cerebral perfusion pressure (CPP) (CPP = mean arterial pressure [MAP] − ICP) and prevent the herniation of brain tissue between intracranial compartments or through the foramen magnum (Fig. 57.1).[1] When the cranium is open, the issue may be to provide relaxation of the intracranial contents to facilitate surgical access or, in extreme circumstances, reverse ongoing brain herniation through the craniotomy site. The principles that apply are similar whether the cranium is open or closed.

The various clinical indicators of increased ICP include headache (particularly headache that awakens the patient at night), nausea and vomiting, blurred vision, somnolence, and papilledema. Computed tomography (CT) findings suggestive of either increased ICP or reduced intracranial compliance reserve include midline shift, obliteration of the basal cisterns, loss of sulci, ventricular effacement (or enlarged ventricles in the event of hydrocephalus or ventricular trapping), and edema. Edema appears on a CT scan as a region of hypodensity. The basal cisterns appear on CT as a dark (hypodense fluid) halo around the upper end of the brainstem (Fig. 57.2). They include the interpeduncular cistern, which lies between the two cerebral peduncles, the quadrigeminal cistern, which overlies the four colliculi, and the ambient cisterns, which lie lateral to the cerebral peduncles.

Fig. 57.3 presents the volume-pressure relationship of the intracranial space. The plateau phase occurring at low volumes reveals that the intracranial space is not completely closed, which confers some compensatory latitude. Compensation is accomplished principally by the translocation of cerebrospinal fluid (CSF) and venous blood to the spinal CSF space and the extracranial veins, respectively.

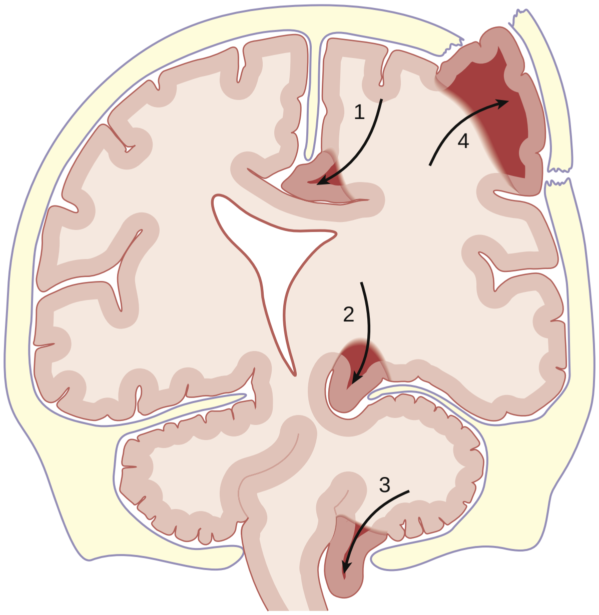

Fig. 57.1 Schematic representation of various herniation pathways. *(1)* Sub-falcine, *(2)* uncal (transtentorial), *(3)* cerebellar, and *(4)* transcalvarial. (From Fishman RA. Brain edema. *N Engl J Med.* 1975;293:706–711.)

Ultimately, when the compensatory potential is exhausted, even tiny incremental increases in volume can substantially increase ICP. These increases have the potential to result in either herniation of brain tissue from one compartment to another (or into the surgical field) (see Fig. 57.1), with resultant mechanical injury to brain tissue, or in reduction of perfusion pressure, leading to ischemic injury.

Several variables can interact to cause or aggravate intracranial hypertension (Fig. 57.4). For clinicians faced with the problem of managing increased ICP, the objective is, broadly speaking, to reduce the volume of the intracranial contents. For mnemonic purposes, the clinician can divide the intracranial space into four subcompartments (Table 57.1): cells (including neurons, glia, tumors, and extravasated collections of blood), fluid (intracellular and interstitial), CSF, and blood.

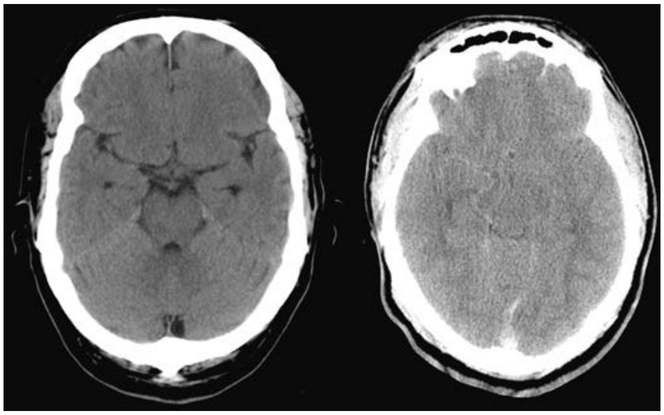

Fig. 57.2 Computed tomography scan depicting normal *(left)* and compressed *(right)* basal cisterns. The basal, or perimesencephalic, cerebrospinal fluid space consists of the interpeduncular cistern (anterior), the ambient cisterns (lateral), and the quadrigeminal cisterns (posterior). In the right panel, the cisterns have been obliterated in a patient with diffuse cerebral swelling (caused by sagittal sinus thrombosis). (Courtesy Ivan Petrovitch, MD.)

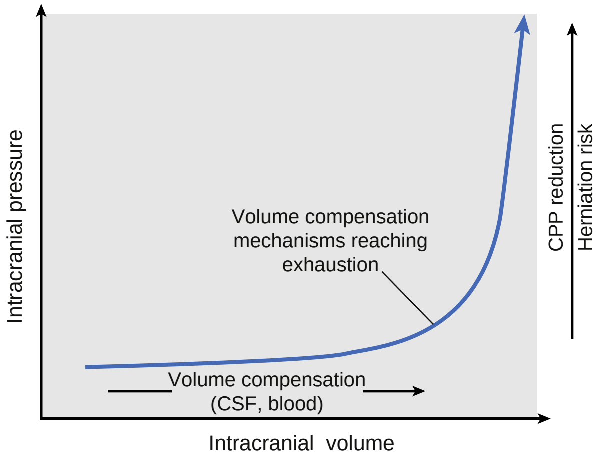

Fig. 57.3 The intracranial volume-pressure relationship. The horizontal portion of the curve indicates that there is initially some latitude for compensation in the face of an expanding intracranial lesion. That compensation is accomplished largely by displacement of cerebrospinal fluid *(CSF)* and venous blood from intracranial to extracranial spaces. Once the compensatory latitudes are exhausted, small-volume increments result in large increases in intracranial pressure with the associated hazards of herniation or of decreased cerebral perfusion pressure *(CPP)*, resulting in ischemia.

Fig. 57.4 The pathophysiology of intracranial hypertension. The figure depicts the manner in which increases in the volumes of any or all of the four intracranial compartments, blood, cerebrospinal fluid *(CSF)*, fluid (interstitial or intracellular), and cells, result in intracranial pressure *(ICP)* increases and eventual neurologic damage. The elements that are most readily under the control of the anesthesiologist are indicated with asterisks *(*)*. (Control of CSF volume requires the presence of a ventriculostomy catheter.) *BP*, Blood pressure; *$PaCO_2$*, partial pressure of carbon dioxide in the arterial blood; *PaO_2*, partial pressure of oxygen in the arterial blood.

1. *The cellular compartment.* This compartment is largely the province of the surgeon. However, it may be the anesthesiologist's responsibility to pose a well-placed diagnostic question. When the brain is bulging into the surgical field at the conclusion of evacuation of an extra-axial hematoma, the clinician should ask whether a subdural or extradural hematoma is present on the contralateral side that warrants either immediate burr holes or immediate postprocedure radiologic evaluation.
2. *The CSF compartment.* There is no pharmacologic manipulation of the CSF space with a time course and magnitude that is relevant to the neurosurgical operating room. The only practical means of manipulating the size of this compartment is by drainage. A tight surgical field can sometimes be improved by passage of a brain needle by the surgeon into a lateral ventricle to drain CSF. Lumbar CSF drainage can be used to improve surgical exposure in situations with no substantial hazard of uncal or transforamenal magnum herniation.

3. *The fluid compartment.* This compartment can be addressed with steroids and osmotic/diuretic agents. The use of these agents is discussed later.
4. *The blood compartment.* This compartment receives the anesthesiologist's greatest attention because it is the most amenable to rapid alteration. The blood compartment should be viewed as having two separate components: venous and arterial.

With respect to the blood compartment, the venous side of the circulation should initially be considered. It is largely a passive compartment and is often overlooked. Despite this passivity, engorgement of this compartment is a common cause of increased ICP or poor conditions in the surgical field (Fig. 57.5). A head-up posture to ensure good venous drainage is the standard in neurosurgical anesthesia and critical care. Obstruction of cerebral venous drainage by extremes of head position or circumferential pressure (cervical collars, endotracheal tube ties) should be avoided. Anything that causes increased intrathoracic pressure can also result in obstruction of cerebral venous drainage. Relevant phenomena include kinking or partial obstruction of endotracheal tubes, tension pneumothorax, coughing or straining against the endotracheal tube, or gas trapping as a result of bronchospasm. Neuromuscular blockade is usually induced during craniotomies unless a contraindication is present. Such a blockade would prevent a sudden cough that can cause a dramatic herniation of cerebral structures through the craniotomy.

Thereafter, the arterial side of the circulation should be considered. Attention to the effect of anesthetic drugs and techniques on cerebral blood flow (CBF) (see Chapter 11) is an established part of neuroanesthesia because, in general, increases in CBF are associated with increases in cerebral blood volume (CBV).[2-4] The notable exception to this rule occurs in the context of cerebral ischemia caused by hypotension or vessel occlusion, at which times CBV may increase as the cerebral vasculature dilates in response to a sudden reduction in CBF. However, the relationship generally applies, and attention to the control of CBF is relevant in situations in which intracranial volume compensation mechanisms are exhausted or ICP is already increased. The general approach is to select anesthetics and to control physiologic variables in a manner that avoids unnecessary increases in CBF. The variables that influence CBF are listed in Box 57.2 and are discussed in Chapter 11.

TABLE 57.1 Intracranial Compartments and Techniques for Manipulation of Their Volume

Compartment	Volume Control Methods
1. Cells (including neurons, glia, tumors, and extravasated blood)	Surgical removal
2. Fluid (intracellular and extracellular)	Diuretics osmotic/diuretic agents Steroids (principally tumors)
3. Cerebral spinal fluid	Drainage
4. Blood	
Arterial side	Decrease cerebral blood flow
Venous side	Improve cerebral venous drainage

BOX 57.2 Factors that Influence Cerebral Blood Flow

See effects of anesthetics on cerebral blood flow and cerebral metabolic rate in Chapter 11 for detailed discussion.

- PaO_2
- $PaCO_2$
- Cerebral metabolic rate
  - Arousal/pain
  - Seizures
  - Temperature
  - Anesthetics
- Blood pressure/status of autoregulation
- Vasoactive agents
  - Anesthetics
  - Pressors
  - Inotropes
  - Vasodilators
- Blood viscosity
- Neurogenic pathways (intra- and extra-axial)

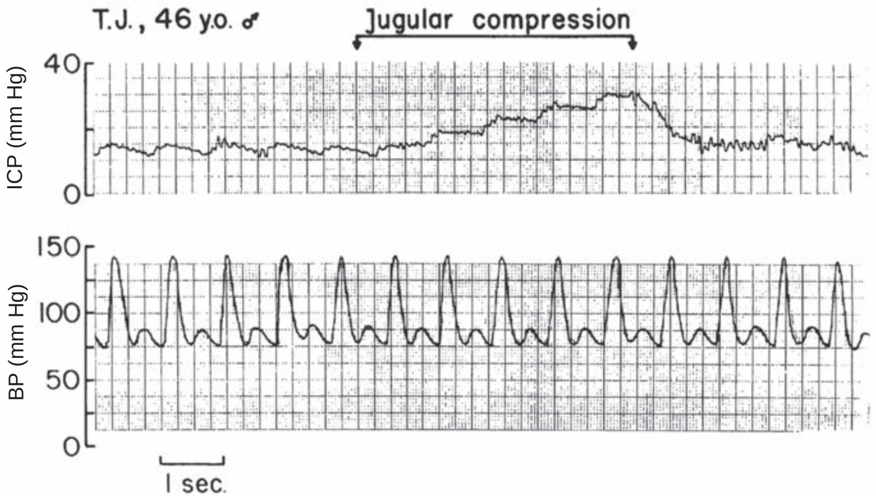

Fig. 57.5 The effect of cerebral venous outflow obstruction on intracranial pressure *(ICP)* in a patient with an intracerebral hematoma. Bilateral jugular compression was applied briefly to verify the function of a newly placed ventriculostomy. The ICP response illustrates the importance of maintaining unobstructed cerebral venous drainage.

SELECTION OF ANESTHETICS

The question of which anesthetics are appropriate, especially in the context of unstable ICP, arises frequently. Chapter 11 provides relevant information in detail, and only broad generalizations are described here.

In general, intravenous anesthetic, analgesic, and sedative drugs are associated with parallel reductions in CBF and cerebral metabolic rate (CMR) and consequently will not have adverse effects on ICP. Ketamine, given in large doses to patients with a generally normal level of consciousness before anesthesia, is the exception. Autoregulation and carbon dioxide (CO_2) responsiveness are generally preserved during the administration of intravenous anesthetics (see Chapter 11).

By contrast, all the volatile anesthetics can be, depending on physiologic and pharmacologic circumstances, dose-dependent cerebral vasodilators. The order of vasodilating potency is approximately halothane → enflurane → desflurane → isoflurane → sevoflurane. As noted in Chapter 11, the CBF differences among desflurane, isoflurane, and sevoflurane are unlikely to be clinically significant. The net CBF effect of a volatile anesthetic depends on the interaction of several factors: the concentration of the anesthetic, the extent of previous CMR depression, simultaneous blood pressure changes acting in conjunction with previous or anesthetic-induced autoregulation abnormalities, and simultaneous changes in partial pressure of carbon dioxide in the arterial blood ($PaCO_2$) acting in conjunction with any disease-related impairment in CO_2 responsiveness.

Nitrous oxide (N_2O) can also be a cerebral vasodilator. The CBF effect of N_2O is greatest when it is administered as a sole anesthetic; least when it is administered against a background of narcotics, propofol, or benzodiazepines; and intermediate when it is administered in conjunction with volatile anesthetics (see Chapter 11).

Despite the vasodilatory potential of both N_2O and volatile anesthetics, experience dictates that both, with the latter in concentrations less than the minimum alveolar concentration (MAC), can be used in most elective and many emergent neurosurgical procedures when administered as part of a balanced anesthetic technique in combination with opioids. However, there are exceptions. Because both N_2O and volatile anesthetics can be vasodilators in some circumstances, when the compensatory latitude of the intracranial space has been exhausted and physiology is abnormal, omitting them on a just-in-case basis may be prudent. In a somnolent, vomiting patient with papilledema, a large tumor mass, and compressed basal cisterns; or in a traumatic brain injury (TBI) victim with an expanding mass lesion or obliterated cisterns and sulci on CT, a predominantly intravenous technique should be used until the cranium and dura are open. Thereafter, the effect of the anesthetic technique can be assessed by direct observation of the surgical field. Although inhaled anesthetics are entirely acceptable components of most anesthetics for neurosurgery, in circumstances in which ICP is persistently increased or the surgical field is persistently "tight," N_2O and volatile anesthetics[5,6] should be replaced by intravenous anesthetics.

Neuromuscular blockers that can release histamine (e.g., atracurium) should be given in small, divided doses. Although succinylcholine can increase ICP, the increases are small and transient. Moreover, the increases can be blocked by a preceding dose of nondepolarizing neuromuscular blocking drugs and, in at least some instances, are not evident in patients with common emergency neurosurgical conditions (TBI, SAH).[7,8] Succinylcholine in conjunction with proper management of the airway and MAP can be used when rapid endotracheal intubation is needed.

From the material just presented and from the discussion of cerebral physiology in Chapter 11, a systematic clinical approach should follow easily. A schema for approaching the problem of an acute increase in ICP or acute deterioration in conditions in the surgical field is presented in Box 57.3.

If the problem has not resolved satisfactorily after following the approach in Box 57.3, Box 57.4 presents options for resolution. CSF drainage was discussed earlier. Additional hyperosmolar solutions are frequently used (see the subsequent section Osmotherapy and Diuretics). Barbiturates have long been the most widely used drugs for inducing reduction in CMR, with the objective of causing a coupled

BOX 57.3 High Intracranial Pressure ("Tight Brain") Checklist

1. Are the relevant pressures controlled?
    a. Jugular venous pressure
        i. Extreme head rotation or neck flexion?
        ii. Direct jugular compression?
        iii. Head-up posture?
    b. Airway pressure
        i. Airway obstruction?
        ii. Bronchospasm?
        iii. Straining, coughing; adequately relaxed?
        iv. Pneumothorax?
        v. Excessive PEEP or APR ventilation?
    c. Partial pressure of CO_2 and O_2 ($PaCO_2$, PaO_2)
    d. Arterial pressure
2. Is the metabolic rate controlled?
    a. Pain/arousal?
    b. Seizures?
    c. Febrile?
3. Are any potential vasodilators in use?
    a. N_2O, volatile agents, nitroprusside, calcium channel blockers?
4. Are there any unrecognized mass lesions?
    a. Hematoma
    b. Air ± N_2O
    c. CSF (clamped ventricular drain)

APR, Airway pressure release; *CSF,* cerebrospinal fluid; *PEEP,* positive end-expiratory pressure.

BOX 57.4 Methods for Rapid Reduction of Intracranial Pressure and Brain Volume (After Review of the Checklist in Box 57.3)

- Further reduction of $PaCO_2$ (to not <23-25 mm Hg)
- CSF drainage (ventriculostomy, brain needle)
- Diuresis (usually mannitol)
- CMR suppression (barbiturates, propofol)
- MAP reduction (if dysautoregulation)
- Surgical control (i.e., lobectomy or removal of bone flap)

CMR, Cerebral metabolic rate; *MAP,* mean arterial pressure.

reduction in CBF and CBV. Propofol has gained popularity for this application. However, although the use of barbiturates is supported by ICU experience demonstrating efficacy in ICP control[9] (if not outcome), little such evidence has been accumulated for propofol. Furthermore, a frequently fatal syndrome of metabolic acidosis and rhabdomyolysis has been recognized in patients who have received prolonged propofol infusions in the ICU setting.[10-12]

MANAGEMENT OF PaCO2

The anesthesiologist and the surgeon should agree on the objectives with respect to $Pa\text{CO}_2$. Induction of hypocapnia was once a routine part of the management of intracranial neurosurgical procedures. The rationale is principally that the concomitant reduction in CBF (see Chapter 11, Fig. 11.9) and CBV will result in a reduction in ICP, or "brain relaxation." The rationale is valid.[13] However, two considerations should influence the clinician's use of hyperventilation. First, the vasoconstrictive effect of hypocapnia can cause ischemia in certain situations. Second, the CBF-lowering and ICP-lowering effect is not sustained for prolonged time periods.[14]

Hypocapnia-Induced Cerebral Ischemia

A normal brain is unlikely to be damaged by the typical clinical use of hyperventilation. However, this may not be the case in certain pathologic conditions.

Normal Brain. Available data[15-19] indicate that in normal subjects, ischemia will not occur at a $PaCO_2$ greater than 20 mm Hg. However, in one investigation,[18] electroencephalogram (EEG) abnormalities and paresthesia occurred in volunteers hyperventilating to $PaCO_2$ values less than 20 mm Hg, and these effects were reversed by hyperbaric oxygenation, suggesting that they may truly have been caused by ischemia. Accordingly, given that a $PaCO_2$ of less than 20 to 25 mm Hg offers very little additional benefit in terms of improvement in intracranial compliance, acute reduction of $PaCO_2$ should be no more than 22 to 25 mm Hg in previously normocapnic persons.

Injured Brain. Preventing herniation, maintaining ICP less than 20 mm Hg, minimizing retractor pressure, and facilitating surgical access remain priorities that may justify hypocapnia. Yet hyperventilation is potentially deleterious and should not be overused. Hyperventilation can result in ischemia,[20,21] especially when baseline CBF is low, as is commonly the case in the first 24 hours after injury.[22-24] An increased frequency of brain regions with very low CBF has been demonstrated in head-injured patients who were acutely hyperventilated.[20,21,25] In addition, low levels of jugular venous oxygen saturation ($SjvO_2$) can be increased by reducing the degree of hyperventilation.[26-28]

The deleterious effect of hyperventilation is difficult to prove. Muizelaar and colleagues[29] performed a study that included a near normocapnic group in which $PaCO_2$ was maintained at approximately 35 mm Hg, and a hypocapnic group in which $PaCO_2$ was maintained in the vicinity of 25 mm Hg. Outcomes at 3 and 6 months after injury were not different. However, in a subset of patients with the best initial motor scores, outcome was better in the normocapnic group. These patients with good motor scores probably represented a subgroup in which the severity of injury was such that, although they needed tracheal intubation, hyperventilation was not necessarily required for control of ICP and who therefore had little to gain from hyperventilation. Thus, prophylactic hyperventilation seemed inadvisable. That conclusion has been extrapolated far beyond the circumstances of relatively mild TBI.

Hyperventilation should not be an automatic component of every neuroanesthetic. There should be an indication for its institution (usually increased or uncertain ICP or the need to improve conditions in the surgical field, or both). Hyperventilation has the potential to cause an adverse effect and should be withdrawn as the indication for it subsides. The concern regarding the hazards of hypocapnia, which evolved in the context of TBI, has influenced all of neurosurgery. In particular, it is now widely avoided in the management of SAH because of the low CBF state that is known to occur.[30,31] In addition, brain tissue beneath retractors can have a similarly reduced CBF.[32,33] However, hyperventilation, used as briefly as possible, is still very much a component of rescue therapy, when herniation is imminent or in progress, or when conditions in the surgical field are too difficult to allow surgery to proceed.

Duration of Hypocapnia-Induced Reduction in Cerebral Blood Flow

The effect of hypocapnia on CBF is not sustained. Fig. 57.6 is a nonquantitative representation of changes in CBF and CSF pH occurring in association with a sustained period of hyperventilation. With the onset of hyperventilation, the pH of both CSF and the brain's extracellular fluid space increases, and CBF decreases abruptly. However, the cerebral alkalosis is not sustained. By alterations in function of the enzyme carbonic anhydrase, the concentration of bicarbonate in CSF and the brain's extracellular fluid space is reduced, and with a time course of 8 to 12 hours, the pH of these compartments returns to normal. Simultaneously,

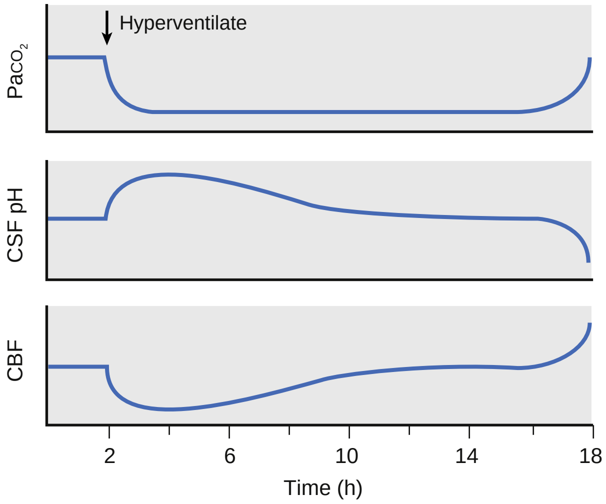

Fig. 57.6 Partial pressure of carbon dioxide in the arterial blood *($PaCO_2$)*, cerebral blood flow *(CBF)*, and cerebrospinal fluid *(CSF)* pH changes with prolonged hyperventilation. Although the decreased arterial $PaCO_2$ (and the systemic alkalosis) persists for the duration of the period of hyperventilation, the pH of the brain and CBF return toward normal over 8 to 12 hours.

CBF returns toward normal levels.[34,35] The implications are twofold. First, patients should be hyperventilated for only as long as a reduction in brain volume is required. Prolonged, unnecessary hyperventilation can lead to a circumstance wherein subsequent events call for additional maneuvers to reduce the volume of the intracranial contents, and then incremental hyperventilation is not efficacious. If, after adaptation, $PaCO_2$ is already in the 23 to 25 mm Hg range, additional hyperventilation may risk pulmonary barotrauma. Second, in a patient who has been hyperventilated for a sustained period (e.g., 2 days in an ICU setting), restoration of $PaCO_2$ from values in the vicinity of 25 mm Hg to typical normal values (e.g., 40 mm Hg) should ideally be accomplished slowly. A sudden increase in $PaCO_2$ from 25 to 40 mm Hg in a patient who has been chronically hyperventilated will have the same physiologic effect that a rapid change from 40 to 55 mm Hg would have in a previously normocapnic patient.

If hypocapnia has been required as an adjunct to brain relaxation during craniotomy, $PaCO_2$ should also be allowed to increase once the retractors are removed (if dural closure requirements permit) to minimize the residual intracranial pneumatocele (see the section on Pneumocephalus).

MANAGEMENT OF ARTERIAL BLOOD PRESSURE

Acceptable arterial blood pressure limits should similarly be agreed on at the beginning of a neurosurgical procedure. One of the prominent themes of contemporary neurosurgery is that CPP should be maintained at normal or even high-normal levels after acute central nervous system insults and during most intracranial neurosurgical procedures. This concept has evolved from the growing appreciation that CBF is frequently very low in some brain regions after acute neurologic insults, in particular TBI and SAH. Two additional factors should be considered. The first is that the autoregulatory response to decreasing blood pressure may not be intact throughout the brain. Fig. 57.7 depicts the ischemic hazard that attends the circumstance of a low resting CBF and absent autoregulation even at blood pressure levels considered safe when autoregulation is intact. In addition, maintenance of arterial pressure is also relevant to brain compressed under retractors [32] because the effective perfusion pressure is lowered by increased local tissue pressure.

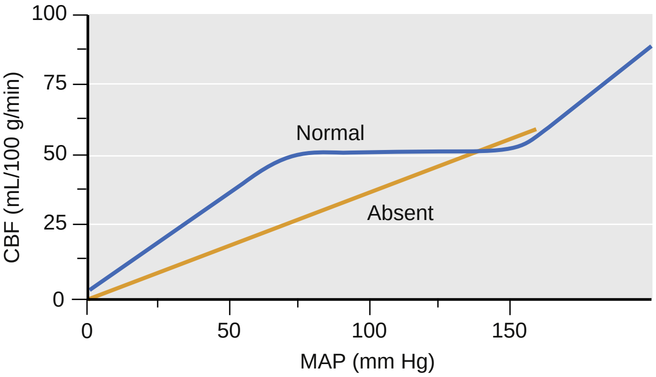

Fig. 57.7 Normal and absent autoregulation curves. The "absent" curve indicates a pressure-passive condition in which cerebral blood flow *(CBF)* varies in proportion to cerebral perfusion pressure (CPP). This curve is drawn to indicate subnormal CBF values during normotension, as have been shown to occur immediately after head injury[26] and subarachnoid hemorrhage.[30] The potential for modest hypotension to cause ischemia is apparent. *MAP,* Mean arterial pressure.

Although the only supportive data are anecdotal, we believe that an aggressive attitude toward arterial blood pressure support should also be given to patients who have sustained a recent spinal cord injury (SCI). This also applies to a spinal cord that is under compression, at risk for compression or vascular compromise because of a disease process (most commonly cervical spinal stenosis with or without ossification of the posterior longitudinal ligament) or an intended surgical procedure, and to those patients undergoing surgery involving retraction of the spinal cord. We believe that arterial blood pressure during anesthesia in these patients should be maintained as closely as possible to, and certainly within, 10% of average awake values.

STEROIDS

The administration of steroids for the purpose of reducing or limiting the formation of edema has a well-established place in neurosurgery. The efficacy of steroids in reducing edema associated with tumors[36-39] and radiation-induced necrosis is well confirmed, but not the edema associated with any other intracranial pathology. Although the time course of this effect is relatively rapid, it is too slow for the management of acute intraoperative events. However, administration beginning 48 hours before an elective surgical procedure has the potential to reduce edema formation and improve the clinical condition by the time of craniotomy.[45] Although clinical improvement occurs within 24 hours,[40] a reduction in ICP may not occur for 48 to 72 hours after the initiation of therapy.[49] Steroids somehow improve the viscoelastic properties of the intracranial space before a reduction in edema occurs, although the mechanism remains undefined.[41] The practice of administering steroids to patients with TBI has been abandoned as a result of controlled trials that demonstrated either no benefit or deleterious effects.[42]

OSMOTHERAPY AND DIURETICS

Hyperosmolar agents and diuretics are used widely in neurosurgery and neurocritical care to reduce the volume of the brain's intracellular and extracellular fluid compartments. Both osmotic and loop diuretics have been used. Although loop diuretics can be effective,[43] hyperosmolar agents are more widely used.

Mannitol

Mannitol is used most commonly intraoperatively because of its long history of rapid and effective reduction of brain volume. The doses vary from 0.25 g/kg to 100 g, with 1.0 g/kg the most common dose. A systematic study in TBI demonstrated that an equivalent initial ICP-reducing effect can be achieved with 0.25 g/kg, although the duration of effect is reduced compared to larger doses.[44] More recent studies reported better surgical brain relaxation scores with higher doses (1-1.5 g/kg) of mannitol compared to a dose of 0.25 g/kg.[45] Mannitol should be administered by infusion (e.g., over 10-15 minutes). Sudden exposure of the cerebral circulation to extreme hyperosmolarity can have a vasodilatory effect, which can produce brain engorgement and increased ICP, both of which do not occur with slower administration.

Mannitol enters the brain and, over a reasonably short time course, appears in the CSF space.[46] The possibility that the mannitol that gains access to the parenchyma aggravates swelling has resulted in varying degrees of reluctance among clinicians to administer mannitol.[47] Most clinicians nonetheless find it to be a mainstay of ICP management. There is the concern that it will only be effective when some degree of blood-brain barrier (BBB) integrity is preserved in a significant portion of the brain. Clinicians respond to this concern by making empiric use of this agent; that is, if it is effective in reducing ICP or improving conditions in the surgical field, repeated doses are administered. The use of hyperosmolar agents is theoretically limited by an upper acceptable osmolarity limit of approximately 320 mOsm/L (although the data supporting the validity of that limit are soft[48]). However, in life-threatening situations, the use is frequently empiric, and incremental doses (e.g., 12.5 g of mannitol) are administered until a clinical response is no longer observed.

Hypertonic Saline

In the critical care environment, the use of hypertonic saline (HTS) in place of mannitol is increasing.[49] Although the initial ICP effects of equiosmolar doses of mannitol and HTS are very similar,[50-53] HTS may have some advantages in the ICU, where repeated administration makes the adverse effects (e.g., diuresis, renal injury) more likely to have clinical significance. In addition, there are anecdotal reports of HTS being effective in patients who were refractory to mannitol.[54,55] Although there is enthusiasm for HTS,[54,56,57] supporting data are limited.[58,59] Furthermore, because of the variations in HTS concentrations (3%, 7.5%, 15%, 23.4%) and osmolar loads in the various studies, it is difficult to make specific recommendations.

Diuretic Combinations

The combination of a loop diuretic (usually furosemide) and an osmotic diuretic is sometimes used. The superficial rationale is that mannitol establishes an osmotic gradient that draws fluid out of brain parenchyma and that the furosemide, by hastening excretion of water from the intravascular space, facilitates the maintenance of that gradient. A second mechanism may add additional justification for the practice of combining the two diuretics. Neurons and glia have homeostatic mechanisms to ensure regulation of cell volume. Neurons and glia that shrink in response to an increased osmolarity in the external environment recover their volume rapidly as a consequence of the accumulation of so-called *idiogenic osmoles*, which serve to minimize the gradient between the internal and external environments. One of those idiogenic osmoles is chloride. Loop diuretics inhibit the chloride channel through which this ion must pass and thereby retard the normal volume-restoring mechanism.[60,61] These diuretic combinations may cause hypovolemia and electrolyte disturbances.

The normal volume regulatory mechanisms of neurons and glia may also be relevant to the phenomenon of rebound swelling. Rebound is commonly attributed to the prior use of mannitol and assumed to be a function of the accumulation of mannitol in cerebral tissue. Although possible, the rebound may in fact be hypertonic rebound rather than mannitol rebound. After a sustained period of hyperosmolarity of any etiology, rebound swelling of neurons and glia (which have accumulated idiogenic osmoles) may occur in the event that systemic osmolarity decreases rapidly toward normal levels. Rebound cerebral swelling can certainly occur after an episode of extreme increase in blood glucose concentration. The use of HTS rather than mannitol will not obviate this phenomenon.

ANTICONVULSANTS

The general principle is that any acute irritation of the cortical surface has the potential to result in seizures. This includes acute neurologic events such as TBI and SAH.[62,63] Cortical incisions and brain surface irritation by retractors may similarly be potential foci. Given the relatively benign nature of contemporary anticonvulsants (e.g., levetiracetam), routine administration to patients undergoing most supratentorial craniotomies seems appropriate in the absence of a contraindication. There is no necessity for rapid administration because the intention is to prevent seizures during the postoperative period.

POSITIONING

The intended surgical position and the necessary positioning aids should be agreed upon at the outset. The commonly used positions and positioning aids and supports are listed in Box 57.5 (see Chapter 34).

General Considerations

The prolonged duration of many neurosurgical procedures should be taken into account in all positions. Pressure points should be identified and padded carefully. Pressure and traction on nerves must be avoided. Given the high risk of thromboembolic complications in neurosurgical patients, precautions including graduated compression stockings and sequential compression devices are warranted.[64] For

BOX 57.5 Common Neurosurgical Positions and Positioning Aids

Positions

- Supine
- Lateral (park bench)
- Semi-lateral (Jannetta)
- Prone
- Sitting

Positioning Aids/Supports

- Pin ("Mayfield") head holder
- Radiolucent pin head holder
- Horseshoe head rest
- Foam head support (e.g., Voss, O.S.I., Prone-View)
- Vacuum mattress ("bean bag")
- Wilson-type frame
- Andrews ("hinder binder")-type frame
- Relton-Hall (four-poster) frame

cranial procedures, some component of head-up posturing (e.g., 15-20 degrees) is used to ensure optimal venous drainage. The conspicuous exception occurs with evacuation of a chronic subdural hemorrhage, after which patients are usually nursed flat to discourage reaccumulation of fluid. Patients are occasionally also maintained flat after CSF shunting to avoid overly rapid collapse of the ventricles.

Supine

The supine position is used with the head neutral or rotated for frontal, temporal, or parietal access. Extremes of head rotation can obstruct the jugular venous drainage, and a shoulder roll can attenuate this problem. The head is usually in a neutral position for bifrontal craniotomies and transsphenoidal approaches to the pituitary. The head-up posture is best accomplished by adjusting the operating table to a chaise longue (lawn chair) position (hip flexion, pillows under the knees, slight reverse Trendelenburg). This orientation, in addition to promoting cerebral venous drainage, decreases back strain.

Semilateral

The semilateral position, also known as the Jannetta position, named after the neurosurgeon who popularized its use for microvascular decompression of the fifth cranial nerve, is used for retromastoid access. It is achieved by lateral tilting of the table 10 to 20 degrees combined with a generous shoulder roll. Again, extreme head rotation, sufficient to cause compression of the contralateral jugular vein by the chin, should be avoided.

Lateral

The lateral position can be used for access to the posterior parietal and occipital lobes and the lateral posterior fossa including tumors at the cerebellopontine angle and aneurysms of the vertebral and basilar arteries. An axillary roll is important for preventing brachial plexus injury.

Prone

The prone position is used for spinal cord, occipital lobe, craniosynostosis, and posterior fossa procedures. For cervical spine and posterior fossa procedures, the final position commonly entails neck flexion, reverse Trendelenburg, and elevation of the legs. This orientation serves to bring the surgical field to a horizontal position. There should be a plan for detaching and reattaching monitors in an orderly manner to prevent an excessive monitoring window. Awake tracheal intubation and prone positioning may be warranted in patients with an unstable cervical spine in whom an unchanged neurologic status should be confirmed before induction of anesthesia in the final surgical position. This approach is also sometimes performed in obese patients.

The head can be secured in a pin head holder (applied before the turn) or positioned on a disposable foam head rest or, less frequently, a horseshoe head rest. A complication of the prone position, which requires constant attention, is retinal ischemia and blindness caused by orbital compression causing central retinal vessel occlusion. It must be intermittently confirmed (e.g., every 15 minutes) and after any surgery-related head or neck movement that pressure has not come to bear on the eye. However, not all postoperative vision loss (POVL) is a result of direct orbital compression. Ischemic optic neuropathy actually appears to be a more frequent cause of POVL than pressure-causing occlusion of central retinal vessels. The cause-and-effect relationships associated with ischemic optic neuropathy are uncertain, but low arterial pressure, low hematocrit level, lengthy surgical procedures, and large intravascular volume fluid administration are statistically associated with the phenomenon.[65]

Direct pressure can also result in various degrees of pressure necrosis of the forehead, maxillae, and chin, especially with prolonged spinal procedures. Pressure should be distributed as evenly as possible over facial structures. Other pressure points to check include the axillae, breasts, iliac crests, femoral canals, genitalia, knees, and heels. Traction on the brachial plexus must be avoided and can usually be accomplished by not exceeding a “90-90” position (arms abducted not >90 degrees; elbows extended not >90 degrees) with care taken to ensure that the elbow is anterior to the shoulder to prevent wrapping of the brachial plexus around the head of the humerus. An antisialagogue (e.g., glycopyrrolate) and an adhesive (e.g., benzoin) may help reduce loosening of the tape used to secure the endotracheal tube.

An objective during prone positioning, especially for lumbar spine surgery, is the avoidance of compression of the inferior vena cava. Impairment of vena cava return diverts blood to the epidural plexus and increases the potential for bleeding during spinal surgery. Minimizing vena cava pressure is an objective of all spinal surgery frames and is accomplished effectively by the Wilson, Andrews, and Jackson variants. However, this does introduce a risk of air embolism,[66,67] although severe clinical occurrences have been very infrequent.[68]

Attention should be paid to preventing injury to the tongue in the prone position. With both cervical and posterior fossa procedures, it is frequently necessary to flex the neck substantially to facilitate surgical access. This reduces the anterior-posterior dimension of the oropharynx, and compression ischemia of the base of the tongue (as well as the soft palate and posterior wall of the pharynx) can occur in the presence of foreign bodies (endotracheal tube, esophageal stethoscope, oral airway). The consequence can be macroglossia, caused by accumulation of edema after reperfusion of the ischemic tissue causing airway obstruction of rapid onset after extubation[69] (discussed later). Accordingly, placing unnecessary adjuncts in the oral cavity and pharynx should be avoided. Omitting the oral airway entirely is unwise because the tongue may then protrude between and be trapped by the teeth as progressive swelling of facial structures occurs during a prolonged prone procedure. A rolled gauze bite block prevents this problem without adding bulk to the oropharynx.

Sitting

There have been several reviews of numerous experiences with the sitting position.[70-74] All concluded that the sitting position can be used with acceptable rates of morbidity and mortality. However, these reports were prepared by groups that perform 50 to 100 or more of these procedures per year, and the hazards of the sitting position may be more frequent for teams who have fewer occasions to use it. The sitting position can be avoided by using one of its alternatives (prone, semilateral, lateral). However, this position will continue to be used because even surgeons who are inclined to use alternative positions may opt for it when access to midline structures (e.g., the quadrigeminal plate, the floor of the fourth ventricle, the pontomedullary junction, and the vermis) is required. Nonetheless, alternative positions for posterior fossa surgery are available and should be considered when contraindications to the sitting position exist.

Achieving the Sitting Position. The properly positioned patient is more commonly in a modified recumbent position as shown in Fig. 57.8 rather than truly sitting. The legs should be kept as high as possible (usually with pillows under the knees) to promote venous return. The head holder should be attached to the back portion of the table (see Fig. 57.8*A*) rather than to the portions under thighs or legs[75] (see Fig. 57.8*B*). This permits lowering of the head and closed chest compressions, if necessary, without the necessity of first taking the patient out of the head holder.

When procedures are performed in the sitting position, the clinician should think in terms of measuring and maintaining perfusion pressure at the level of the surgical field. This is best accomplished by referencing transducers to the level of the external auditory canal. If a manual blood pressure cuff on the arm is used, a correction* to allow for the hydrostatic difference between the arm and the operative field should be applied.

A series of hazards are associated with the sitting position. Circulatory instability, macroglossia, and quadriplegia are discussed in this section. Pneumocephalus is discussed in its own section. Venous air embolism (VAE) and paradoxical air embolism (PAE) are discussed in the section Venous Air Embolism. Several of these hazards are also relevant when cervical spine and posterior fossa procedures are performed in non-sitting positions but occur with greater frequency in the sitting position.

Cardiovascular Effects of the Sitting Position. Hypotension should be avoided. Prepositioning hydration, compressive stockings, and slow, incremental adjustment of table position are appropriate. Intravenous vasopressor administration may be required in some patients. However, in most healthy patients the hemodynamic changes are of a nonthreatening magnitude. In a study of healthy anesthetized adults aged 22 to 64 years old, relatively modest changes were observed.[76] MAP was relatively unaffected, whereas wedge pressure, stroke volume, and cardiac index decreased—the latter by approximately 15%—although there was some variation with the anesthetics used. The combination of an unchanged MAP (which in general requires the use of a light, high sympathetic tone anesthetic) and a reduced cardiac index implies that systemic vascular resistance (SVR) increased. Their calculations and the observations of other investigators [77] reveal significant increases in SVR. For patients in whom an abrupt increase in SVR may be poorly tolerated, the sitting position may represent a physiologic threat and alternative positions should be considered.

During procedures performed in the sitting position, MAP should be transduced at or corrected to head level to provide a meaningful index of CPP. Specifically, CPP (MAP – estimated ICP) should be maintained at a minimum value of 60 mm Hg in healthy patients in whom it is reasonable to assume a normal cerebral vasculature. The safe lower limit should be raised for elderly patients, for those with hypertension or known cerebral vascular disease, or for those with degenerative disease of the cervical spine or cervical spinal stenosis who may be at risk for decreased spinal cord perfusion, and in the event that substantial or sustained retractor pressure must be applied to brain or spinal cord tissue.

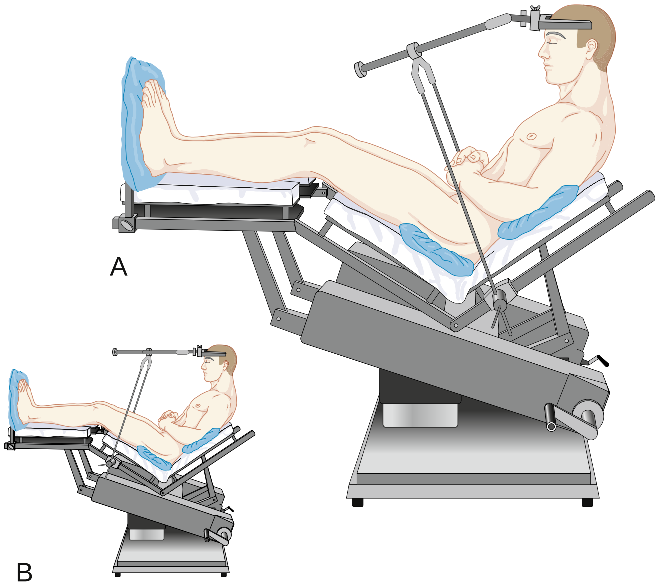

Fig. 57.8 The sitting position. (A) The head-holder support is correctly positioned so that the head can be lowered without the necessity to first detach the head holder. (B) This configuration, with the support attached to the thigh portion of the table, should be avoided. (From Martin JT. *Positioning in Anesthesia and Surgery*. Philadelphia: Saunders; 1988, with permission.)

Macroglossia. There have been sporadic reports of upper airway obstruction after posterior fossa procedures in which swelling of pharyngeal structures, including the soft palate, posterior pharyngeal wall, and base of the tongue, has been observed.[39,69,78] These episodes have been attributed to edema formation at the time of reperfusion after trauma or prolonged ischemia, occurring as the result of foreign bodies (usually oral airways) causing pressure on these structures in the circumstances of lengthy procedures with sustained neck flexion (which is usually required to improve access to posterior structures). It is customary to maintain at least two fingerbreadths between the chin/mandible and the sternum/clavicle to prevent excessive reduction of the anterior-posterior diameter of the oropharynx. Consideration of the macroglossia phenomenon may also be relevant as clinicians contemplate the use of transesophageal echocardiography (TEE) in the neurosurgery suite. The centers that routinely use TEE in neurosurgery mostly use pediatric diameter probes to avoid trauma to pharyngeal and perilaryngeal structures.

Quadriplegia. The sitting position has been implicated as a cause of rare instances of unexplained postoperative quadriplegia. It has been hypothesized[79] that neck flexion, a common concomitant of the seated position, may result in stretching or compression of the cervical spinal cord. This possibility may represent a relative contraindication to the use of this position in patients with significant degenerative disease of the cervical spine, especially when there is evidence of associated cerebral vascular disease. The arterial blood pressure management implications are mentioned in the preceding section on cardiovascular effects. It may also represent a justification for evoked response monitoring during the positioning phase of a sitting procedure for patients perceived to be at high risk (also see Chapter 39).

---

* A column of blood 32 cm high exerts a pressure of 25 mm Hg.

PNEUMOCEPHALUS

The issue of pneumocephalus arises most often in connection with posterior fossa craniotomies performed with a head-up posture.[80,81] During these procedures, air may enter the supratentorial space, much as air enters an inverted pop bottle. Depending on the relationship of the brainstem and temporal lobes to the incisura, the pressure in the air collection may or may not be able to equilibrate with atmospheric pressure. This phenomenon has relevance to the use of N_2O because any N_2O that enters a trapped gas space augments the volume of that space. In those (probably uncommon) intraoperative circumstances where there is, in fact, a completely closed intracranial gas space, the use of N_2O may result in an effect comparable with that of an expanding mass lesion. We do not view N_2O as absolutely contraindicated because, before dural closure, intracranial gas is probably only rarely trapped. Nonetheless, attention to this possibility is important when one is presented with the problem of an increasingly tight brain during a posterior fossa craniotomy.[82,83]

During a posterior fossa procedure done in a head-up posture, when surgical closure has reached a stage such that the intracranial space has been completely sealed from the atmosphere, N_2O should be omitted because of the possibility of contributing to a tension pneumocephalus. Note that the use of N_2O up to the point of dural closure may actually represent a clinical advantage,[84] as in rabbits the gas pocket has been shown to shrink more rapidly because of the presence of N_2O (because N_2O diffuses much more quickly than nitrogen). Tension pneumocephalus is often naively viewed as exclusively a function of the use of N_2O. However, tension pneumocephalus can most certainly occur as a complication of intracranial neurosurgery entirely *unrelated* to the use of N_2O.[85] It is one of the causes of delayed awakening or nonawakening after both posterior fossa and supratentorial procedures (Fig. 57.9).[85,86] It occurs because air enters the cranium when the patient is in a head-up position at a time when the volume of the intracranial contents has been reduced because of some combination of hypocapnia, good venous drainage, osmotic diuresis, and CSF loss from the operative field. When the cranium is closed and the patient is returned to the near supine position, CSF, venous blood, and extracellular fluid return or reaccumulate and the air pocket becomes an unyielding mass lesion (because of the very slow diffusion of nitrogen). It may cause delayed recovery of consciousness or severe headache. Among supratentorial craniotomies, the largest residual air spaces occur after frontal skull base procedures in which energetic brain relaxation measures are used to facilitate subfrontal access (see Fig. 57.9). At the end of these procedures, typically done in a supine/brow-up position, the intracranial dead space cannot be filled with normal saline as is commonly done with smaller craniotomy defects, and there may be a large residual pneumatocele. We doubt that the possible occurrence of this phenomenon represents a contraindication to N_2O. However, withdrawal of N_2O may be appropriate at the time of scalp closure. The diagnosis of pneumocephalus is established by a brow-up lateral radiography or, more commonly, a CT scan. The treatment is a twist-drill hole followed by needle puncture of the dura.

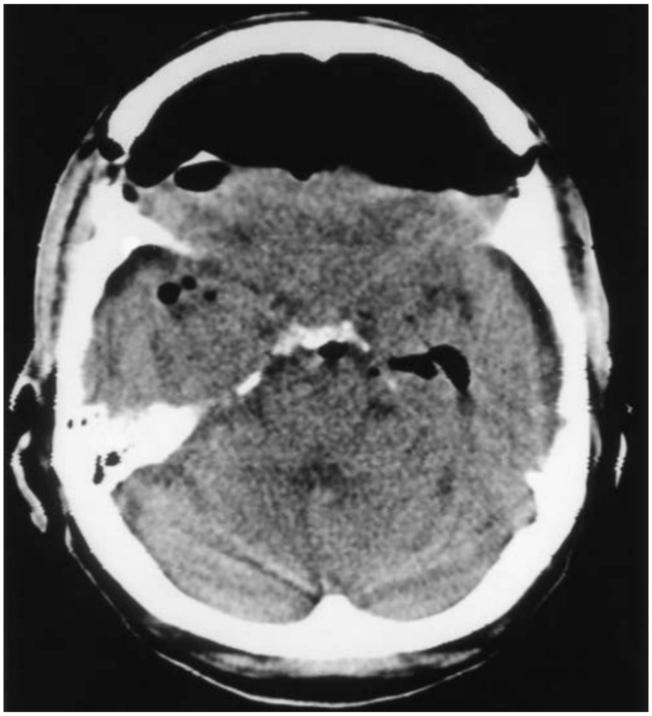

Fig. 57.9 Postoperative computed tomographic scan demonstrating a large pneumocephalus after a subfrontal approach to a suprasellar glioma. Immediately postoperatively, the patient was confused and agitated, and he complained of a severe headache.

Residual intracranial air should be considered at the time of repeat anesthesia, both neurosurgical and nonneurosurgical. Air frequently remains evident on CT scan for more than 7 days after a craniotomy.[87] Pneumocephalus can also develop de novo in the postoperative period in patients who have a residual dural defect and a communication between the nasal sinuses and the intracranial space.[88]

VENOUS AIR EMBOLISM

The incidence of VAE varies according to the procedure, the intraoperative position, and the detection method used. During posterior fossa procedures performed in the sitting position, VAE is detectable by precordial Doppler in approximately 40% of patients and by TEE in as many as 76%.[89-92] The incidence of VAE during posterior fossa procedures performed in nonsitting positions is much less (12% using precordial Doppler in the report of Black and colleagues [72]), and it is probable but unproven that the average volume of air entrained per event is also smaller. The incidence of VAE is apparently lower with cervical laminectomy (25% using TEE in the sitting position versus 76% for posterior fossa procedures[91]). Although VAE is principally a hazard of posterior fossa and upper cervical spine procedures, especially when they are performed in the sitting position, it can occur with supratentorial procedures. The most common situations involve tumors, most often parasagittal or falcine meningiomas, that encroach on the posterior half of the sagittal sinus (Fig. 57.10) and craniosynostosis procedures, typically performed in children.[93,94] Pin sites can also serve as VAE access sites. Accordingly, pin head holders should be removed after the patient has been taken out of significant degrees of the head-up positioning. Spontaneous ventilation (with the attendant intermittent negative intrathoracic pressure) will increase the risk of air entrainment. A 6% incidence of Doppler-detectable VAE was reported in a series of deep-brain stimulator placement procedures performed in spontaneously breathing patients.[95]

The common sources of critical VAE are the major cerebral venous sinuses, in particular the transverse, the sigmoid, and the posterior half of the sagittal sinus, all of which may be noncollapsible because of their dural attachments. Air entry may also occur via emissary veins, particularly from suboccipital musculature, via the diploic space of the skull (which can be violated by both the craniotomy and pin fixation) and the cervical epidural veins. It is believed (but not confirmed by systematic study) that the VAE risk associated with cervical laminectomy is more likely when the exposure requires dissection of suboccipital muscle with the potential to open emissary veins to the atmosphere at their point of entry into occipital bone. There is also anecdotal evidence[96] that air under pressure in the ventricles or subdural space can occasionally enter the venous system, perhaps along the normal egress route of the CSF.

Detection of Venous Air Embolism

The monitors used for the detection of VAE should provide (1) a high level of sensitivity, (2) a high level of specificity, (3) a rapid response, (4) a quantitative measure of the VAE event, and (5) an indication of the course of recovery from the VAE event. The combination of a precordial Doppler and expired CO_2 monitoring meets these criteria and is the current practice in many institutions. Doppler placement in a left or right parasternal location between the second and third or third and fourth ribs has a very high detection rate for gas embolization,[97] and when good heart tones are heard, maneuvers to confirm adequate placement appear to be unnecessary. The TEE is more sensitive than the precordial Doppler (Fig. 57.11) to VAE[98] and offers the advantage of also identifying right-to-left shunting of air. However, its safety during prolonged use (especially with pronounced neck flexion) is not well established. Expired nitrogen analysis is theoretically attractive. However, the expired nitrogen concentrations involved in anything less than catastrophic VAE are very small and push the available instrumentation to the limits of its sensitivity.[99]

Fig. 57.12 presents the physiologic and monitor response to an air embolic event, and Box 57.6 offers an appropriate management response to such an event.

Which Patients Should Have a Right Heart Catheter?

All patients who undergo sitting posterior fossa procedures should have a right heart catheter placed. Although life-threatening VAE is relatively uncommon, a catheter permits immediate evacuation of an air-filled heart. With the nonsitting positions, it is frequently appropriate, after a documented discussion with the surgeon, to omit the right heart catheter. The perceived risks of VAE associated with the intended procedure and the patient's physiologic reserve are the variables that contribute to the decision. Microvascular decompression of the fifth or seventh cranial nerves are examples of procedures for which the right heart catheter is usually omitted. The essentially horizontal semilateral position and the very limited retromastoid craniectomy that is required have resulted (at our institution) in a

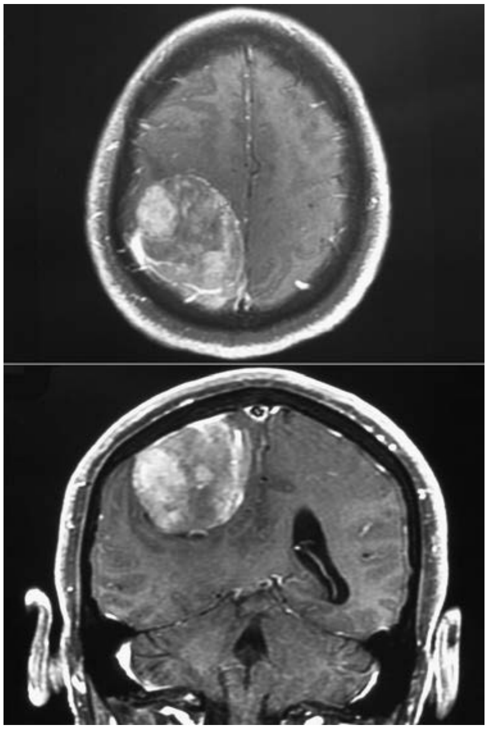

Fig. 57.10 Axial *(top)* and coronal *(bottom)* magnetic resonance images of a parasagittal meningioma. Resection of meningiomas arising from the dural reflection overlying the sagittal sinus or from the dura of the adjacent convexity or falx often entails a risk of venous air embolism because of the proximity of the sagittal sinus (the triangular structure at the superior end of the interhemispheric fissure in the bottom panel).

BOX 57.6 Management of an Acute Air Embolic Event

1. Prevent further air entry
   - Notify surgeon (flood or pack surgical field)
   - Jugular compression
   - Lower the head
2. Treat the intravascular air
   - Aspirate right heart catheter
   - Discontinue N_2O
   - FiO_2: 1.0
   - Pressors, inotropes
   - Chest compression

very low incidence of Doppler-detectable VAE. One should know the local surgical practices, particularly with respect to the degree of head-up posture, before deciding to omit a right atrial catheter. With regard to the Jannetta procedure, the necessary retromastoid craniectomy is performed in the angle between the transverse and sigmoid sinuses, and venous sinusoids and emissary veins in the suboccipital bone are common. If this procedure is performed with any degree of head-up posturing, the risk of VAE may still be substantial.

Which Vein Should Be Used for Right Heart Access?

Although some surgeons may ask that neck veins not be used, a skillfully placed jugular catheter is usually acceptable. In a very limited number of patients, high ICP may make the head-down posture undesirable. In others, unfavorable anatomy with an increased likelihood of a difficult cannulation and hematoma formation may also encourage the use of alternate access sites.

Positioning the Right Heart Catheter

The investigation by Bunegin and colleagues suggested that a multiorificed catheter should be located with the tip 2 cm below the superior vena caval-atrial junction and a single-orificed catheter with the tip 3 cm above the superior vena caval-atrial junction.[100] Although these small distinctions in location may be relevant for optimal recovery of small volumes of air when cardiac output is well maintained, for the recovery of massive volumes of air in the face of cardiovascular collapse, anywhere in the right atrium should suffice. Confirmation of right heart placement can be accomplished by (1) radiography, (2) intravascular electrocardiography (ECG),[101] or (3) TEE.[102] Although there is no literature to support the practice, with catheter access via the right internal jugular vein, a measured placement to the level of the second or third right intercostal space should suffice when the catheter passes readily. The intravascular electrocardiography technique makes use of the fact that an ECG “electrode” placed in the middle of the right atrium will initially “see” an increasing positivity as the developing P-wave vector approaches it (Fig. 57.13), and then an increasing negativity as the wave of atrial depolarization passes and moves away from it. The resultant biphasic P wave is characteristic of an intraatrial electrode position. The technique

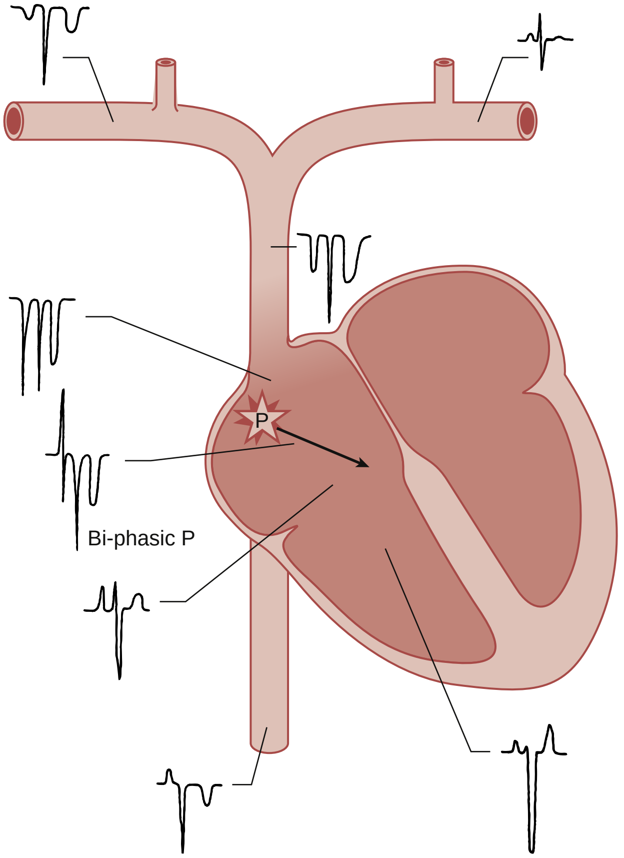

Fig. 57.13 Electrocardiogram (ECG) configurations observed at various locations when a central venous catheter is used as an intravascular ECG electrode. The configurations in the figure will be observed when Lead II is monitored and the positive electrode (the leg electrode) is connected to the catheter. *P* indicates the sinoatrial node. The *black arrow* indicates the P-wave vector. Note the equi-biphasic P wave when the catheter tip is in the mid-right atrial position.[101]

requires that the central venous pressure (CVP) catheter become an exploring ECG electrode. This is accomplished by filling the catheter with an electrolyte solution (bicarbonate is best) and attaching an ECG lead (the leg lead if lead II is selected) to the hub of the CVP catheter. Commercial CVP kits with an ECG adapter are available. The ECG configurations that will be observed at various intravascular locations are shown in Fig. 57.13. To minimize the microshock hazard, a battery-operated ECG unit is preferable, and any unnecessary electrical apparatus should be detached from the patient during catheter placement.

Paradoxical Air Embolism

The possibility of the passage of air across the interatrial septum via a patent foramen ovale (PFO), which is known to be present in approximately 25% of adults, is a concern.[103] The risk is major cerebral and coronary morbidity. However, the precise definition of the morbidity that can actually be attributed to PAE is not clear. Although the minimal pressure required to open a probe PFO is not known with certainty, the necessary gradient may be as much as 5 mm Hg. In a clinical investigation, Mammoto and colleagues observed that PAE occurred only in the context of major air embolic events, suggesting that significant increases in right heart pressures are an important predisposing factor of the occurrence of PAE.[104] Several clinical investigations have examined factors that influence the right atrial pressure (RAP) to left atrial pressure (LAP) gradient. The use of positive end-expiratory pressure (PEEP) increases the incidence of a positive RAP to pulmonary wedge pressure gradient[105] and generous fluid administration (e.g., 2800 mL/patient vs. 1220 mL/control patient[106]) reduces it. As a result, the use of PEEP, which was once advocated as a means of preventing air entrainment, was abandoned. Subsequently, the practice of more generous fluid administration for patients undergoing posterior fossa procedures evolved. However, even when mean LAP exceeds mean RAP, PAE can still occur because transient reversal of the interatrial pressure gradient can occur during each cardiac cycle.[107]

Some centers have advocated performing bubble studies preoperatively with echocardiography[92] or transcranial Doppler (TCD),[108] or intraoperatively using TEE prior to positioning[109] to identify patients with a PFO with a view to using alternatives to the sitting position in this subpopulation.[91,110] Some centers thereafter advocate the use of TEE to identify paradoxical embolization intraoperatively.[91,111] However, none of these practices has become a community-wide standard of care. Furthermore, because the morbid events attributable to PAE have been relatively infrequent, surgeons who are convinced that the sitting position is optimal for a given procedure[74] are loath to be dissuaded from using it on the basis of what may seem like the very minor possibility of an injury to the patient occurring by this mechanism.

Transpulmonary Passage of Air

Air can sometimes traverse the pulmonary vascular bed to reach the systemic circulation.[112-114] Transpulmonary passage is more likely to occur when large volumes of air are presented to the pulmonary vascular filter.[115,116] In addition, pulmonary vasodilators, including volatile anesthetics, may decrease the threshold for transpulmonary passage.[115-117] The magnitude of differences among anesthetics does not appear to mandate any related “tailoring” of anesthetic techniques. However, N_2O should be discontinued promptly after even apparently minor VAE events because of the possibility that air may reach the left-sided circulation either via a PFO or the pulmonary vascular bed.

Box 57.6 presents an approach for responding to an acute VAE event. It includes raising venous pressure by direct compression of the jugular veins. PEEP and the Valsalva maneuver were once advocated. However, both PEEP [105] and the release of a Valsalva maneuver increase the risk of PAE, and the relative superiority of jugular venous compression in raising cerebral venous pressures has been confirmed.[118,119] Furthermore, the impairment of systemic venous return caused by the sudden application of substantial PEEP may be undesirable in the face of the cardiovascular dysfunction already caused by the VAE event.

It has been recommended that a patient who has sustained a hemodynamically significant VAE should be placed in a lateral position with the right side up. The rationale is that air will remain in the right atrium, where it will not contribute to an air lock in the right ventricle and where it will remain amenable to recovery via a right atrial catheter. The first difficulty is that this repositioning is all but impossible with a patient in a pin head holder. In addition, the only systematic attempt to examine the efficacy of this maneuver, albeit performed in dogs, failed to identify any hemodynamic benefit. [120]

Nitrous Oxide

Nitrous oxide diffuses into air bubbles trapped in the vascular tree and, accordingly, N_2O should be eliminated after a clinical VAE event to avoid aggravating the cardiovascular impact. As noted earlier, the PAE phenomenon adds an additional reason for eliminating N_2O *after* the occurrence of VAE. When major VAE occurs, no matter how the RAP-LAP gradient was manipulated before the event, RAP increases abruptly with respect to LAP,[121] and major VAE results in an acutely increased risk of PAE in patients with a PFO.[104] Should N_2O be used in patients at risk for VAE? Some clinicians may decide to simply avoid it. However, N_2O can be used with the knowledge that it neither increases the incidence of VAE[122] nor aggravates the hemodynamic response to VAE provided that it is eliminated when VAE occurs.[123]

MONITORING

Neurologic monitoring techniques are discussed in Chapter 39. Invasive monitoring is frequently appropriate in neurosurgery. Some of the numerous indications for an arterial catheter are listed in Box 57.7.

Patients with increased ICP may be intolerant of the vascular engorgement associated with sudden hypertension occurring as a consequence of light anesthesia. Surgical relief of increased ICP may be associated with sudden hypotension as brainstem compression is relieved. Beat-by-beat arterial pressure monitoring also serves as an important depth of anesthesia monitor and as an early neurologic injury warning system. Much of the brain is insensate. As a consequence, the intradural portion of many neurosurgical procedures is not very stimulating and, to achieve circulatory stability, relatively light anesthesia is often necessary. There should be constant attention to the possibility of sudden arousal (most often associated with cranial nerve traction or irritation). This is especially important when paralysis is precluded by the use of motor-evoked potential monitoring or electromyographic recording from facial muscles to monitor cranial nerve integrity. Blood pressure responses may reveal imminent arousal; they may also serve to warn a surgeon of excessive or unrecognized irritation, traction, or compression of neurologic tissue. These occur most often with posterior fossa procedures involving brainstem or cranial nerves, and abrupt changes should be reported to the surgeon immediately.

The use of right heart catheters for air retrieval is discussed in the section VAE. In the absence of VAE risk and in the presence of good peripheral venous access, we rarely place right heart catheters for neurosurgical procedures. Antecedent cardiac disease may justify a pulmonary arterial catheter. The use of the precordial Doppler is also described in the section VAE.

BOX 57.7 **Relative Indications for Intraarterial Pressure Monitoring**

- Elevated intracranial pressure
- Ischemia or incipient ischemia of neural tissue
  - Recent subarachnoid hemorrhage
  - Recent head injury
  - Recent spinal cord injury
  - Intended or possible temporary vessel occlusion
- Circulatory instability
  - Trauma
  - Spinal cord injury (spinal shock)
  - Sitting position
  - Possible barbiturate coma
- Possibility of induced hypotension
- Possibility of induced hypertension
- Anticipated or potential major blood loss
  - Aneurysm clipping
  - Arteriovenous malformations
  - Vascular tumors
  - Tumors involving or adjacent to major venous sinuses
  - Craniofacial reconstruction
  - Extensive craniosynostosis procedures
- Anticipated light anesthesia without paralysis
- Brainstem manipulation, compression, dissection
- Anticipated CN manipulation (especially CN V)
- Advantageous for postoperative intensive care
  - Hypervolemic therapy
  - Head injury
  - Diabetes insipidus
- Incidental cardiac disease

CN, Cranial nerve.

INTRAVENOUS FLUID MANAGEMENT

The general principles of fluid management for neurosurgical anesthesia are (1) maintain normovolemia and (2) avoid reduction of serum osmolarity. The first principle is a derivative of the concept presented in the section Management of Arterial Blood Pressure, which is that it is generally ideal to maintain a normal MAP in patients undergoing most neurosurgical procedures and neurosurgical critical care. Maintaining normovolemia is simply one element of maintaining a normal MAP. The second principle is a derivative of the observation that lowering serum osmolarity results in edema of both normal and abnormal brain.[124,125] Administering fluids that provide free water (i.e., fluids that do not have sufficient nonglucose solutes to render them iso-osmolar with respect to blood) lowers serum osmolarity if the amount of free water administered is in excess of that required to maintain ongoing free water loss. Normal saline and balanced salt solutions are the fluids most often used intraoperatively. At 308 mOsm/L, normal saline is slightly hyperosmolar with respect to plasma (295 mOsm/L). It has the disadvantage that large volumes can cause hyperchloremic metabolic acidosis.[126] The physiologic significance of this acidosis, which involves the extracellular but not the intracellular fluid space, is unclear. At a minimum, it has the potential to confuse the diagnostic picture when acidosis is present. Comparisons between normal saline and balanced crystalloid solutions in the setting of cardiac surgery[127] and critically ill intensive care patients[128] did not reveal any adverse events (acute kidney injury, mortality, length of hospital stay) attributable to administration of normal saline. Nonetheless, to avoid hyperchloremic metabolic acidosis, many clinicians use lactated Ringer solution.

Although lactated Ringer solution (273 mOsm/L) is in theory not ideal for replacement of blood and third-space loss or insensible losses, it serves as an entirely reasonable compromise for meeting both needs simultaneously and is very suitable in most instances. It is a hypoosmolar fluid, and in a healthy experimental animal, it is possible to reduce serum osmolarity and produce cerebral edema with a large volume of lactated Ringer solution.[125] In the setting of large-volume fluid administration (e.g., significant blood loss, multiple trauma), it is the authors' practice to alternate, liter by liter, lactated Ringer solution and normal saline. Alternatively, Plasma-Lyte (Baxter International Inc.; Deerfield, IL), a buffered crystalloid solution (pH 7.4) with physiochemical properties similar to plasma, may be considered, if available.[129] Plasma-Lyte is considered isotonic with a calculated *in vivo* osmolality range of approximately 270 to 294 mOsmol/kg (depending on the manufacturing country). Although there may be advantages to the use of a physiologically balanced solution such as Plasma-Lyte, there remains insufficient clinical evidence to advocate for one fluid over another at the present time.

The crystalloid versus colloid discussion is a recurrent one. It arises most commonly in the context of the patient with TBI. Although views differ, there has in fact been only a single demonstration that the reduction of colloid oncotic pressure (COP) in the absence of a change of osmolarity can actually contribute to an augmentation of cerebral edema in the setting of experimental head injury.[130] The transcapillary membrane pressure gradients that can be produced by reduction of COP are in fact very small by comparison of those created by changes in serum osmolarity. Nonetheless, it appears that those small gradients, probably in the setting of an experimental BBB injury of intermediate severity, have the potential to augment edema. A fluid administration pattern should be selected that, in addition to maintaining normal serum osmolarity, prevents substantial reductions in COP. For most elective craniotomies, which entail only modest fluid administration, this does not require the administration of colloid solutions. However, in situations requiring substantial volume administration (e.g., multiple trauma, aneurysm rupture, cerebral venous sinus laceration, filling pressure support during barbiturate coma), a combination of isotonic crystalloid and colloid may be appropriate.

Which Colloid Solutions Should Be Used?

Colloid administration has created increasing concern about not only its efficacy but also its safety. Based on empirical local experience, we view albumin to be a reasonable choice. However, there are conflicting opinions and cross-currents in the literature. An analysis of the subset of patients in the SAFE (Saline vs. Albumin Fluid Evaluation) trial with severe TBI (Glasgow Coma Scale [GCS] score 3-8) revealed increased mortality among those who received albumin.[131] However, there are several reasons to be suspicious of that conclusion. First, SAFE trial patients were not originally randomized on the basis of TBI characteristics and, by chance, there were imbalances in TBI-related characteristics that appear to have placed the albumin group at greater risk.[132] Second, the 4% albumin solution used was hypoosmolar (274 mOsm/L) and might have been expected to aggravate edema.[133] Furthermore, there is no compelling physiologic explanation for an albumin-specific hazard. The formation of cerebral edema that is more difficult to clear is an inevitable suspicion.[134] However, if valid, that should be a class effect relevant to all colloids (including fresh frozen plasma and starches) rather than being albumin specific. Furthermore, albumin has been used in TBI by others with no evidence of adverse effects.[135,136] In contrast to alleged adverse effects in the context of TBI, there are potential beneficial effects in SAH.[137,138] The ALIAS phase III clinical trial evaluated the use of albumin in acute stroke patients. Although albumin administration was associated with increased rate of symptomatic intracranial hemorrhage (ICH) and congestive heart failure (CHF), no negative impact was detected in the primary outcome measure—the rate of favorable neurologic outcome at 90 days.[139] At best, the existing literature may justify consideration of limiting albumin volumes in patients with severe head injury. The indications and concerns for colloids, and especially albumin administration, have been recently expressed (see Chapter 47).

The various starch-containing solutions should be used cautiously in neurosurgery because, in addition to a dilutional reduction of coagulation factors, they interfere directly with both platelets and the factor VIII complex.[140] The coagulation effects are proportional to the average molecular weight and the hydroxyethyl group substitution ratio of the starch preparation. There have been several reported instances of bleeding in neurosurgical patients that were attributed to hydroxylethyl starch administration. However, all of those have involved circumstances in which the manufacturer's recommended dosage limit was exceeded[141] or in which the starch was administered up to the recommended limit on successive days, probably resulting in an accumulation effect.[142] The latitudes are wider with the subsequent availability of small molecule/lower substitution ratio preparations. These preparations have a record of safety when used in the operating room in general [143] and have been administered uneventfully to patients with severe TBI.[144] The decision about whether to use these products is frequently a matter of local practice. Although hydroxylethyl starch solutions can be used in neuroanesthesia, clinicians should respect the manufacturers' recommended dose restrictions and should use additional restraint in situations where there are other reasons for impairment of the coagulation mechanism. Recent concern about adverse effects on renal function in patients who have received starches in critical care situations have made some reluctant to use these compounds in any setting. The dextran-containing solutions are generally avoided because of their effects on platelet function.

There is longstanding interest in the use of hypertonic fluids for the resuscitation of polytrauma victims in general, and of patients with TBI in particular. However, there has yet to be a scientifically convincing demonstration of outcome improvement associated with hypertonic solution administration.[145]

GLUCOSE MANAGEMENT

There is a widespread notion that increased plasma glucose aggravates a cerebral ischemic insult. This may be true for an acute ischemic event in a previously normal brain, but that should not be extrapolated to the idea that all "neuro patients" should be submitted to very tight glycemic control. The potential benefits of a lower plasma glucose concentration in the event of an acute ischemic episode (which have not been well confirmed in humans) should be outweighed by the very clear demonstrations that the injured brain (e.g., TBI, SAH) becomes "hypoglycemic" and suffers metabolic distress at plasma glucose levels that are satisfactory for a normal brain.[146-149] This may be because injury can produce a state of hyperglycolysis.[147,150] Although severe hyperglycemia should be treated to reduce infection rates, patients with acute injuries (e.g., TBI, SAH) should not be submitted to very tight control. As one reviewer said, "extra sweetness [is] required" [151] by the injured brain. The authors' intraoperative intervention threshold is 250 mg/dL (14 mmol/L), the objective being to reduce plasma glucose to less than 200 mg/dL (11 mmol/L). One published guideline recommends an ICU objective of less than 180 mg/dL (10 mmol/L) in patients with cerebral injuries but cautions that plasma glucose not be allowed to decrease to less than 100 mg/dL (5 mmol/L).[152] The NICE-Sugar study's control group range of 144 to 180 mg/dL (7.8-10 mmol/L) [153] is probably also a reasonable target. However, control should only be undertaken when processes to prevent hypoglycemia are firmly in place, and the lower the targets, the more comprehensive the hypoglycemia prevention processes must be.

HYPOTHERMIA

The effects of hypothermia on cerebral physiology and its potential cerebral protective mechanisms are presented in Chapter 11. There have been numerous laboratory demonstrations on the efficacy of mild hypothermia (32°C-34°C) in reducing the neurologic injury occurring after standardized cerebral and spinal cord ischemic insults. On that basis, the use of induced hypothermia in the management of cerebral vascular procedures, in particular aneurysms and sometimes AVMs, became widespread. However, an international multicenter trial of mild hypothermia in 1001 relatively good-grade patients undergoing aneurysm surgery revealed no improvement in neurologic outcome.[154] Thus, the routine use of intraoperative hypothermia has inevitably diminished.

Because ischemia is recognized to make a post-insult contribution to neuronal injury after TBI,[26,155] hypothermia was also studied in laboratory models of TBI.[156] Hypothermia was effective and resulted in a prospective multicenter trial in which hypothermia (33°C) was induced within 8 hours of injury and was maintained for 48 hours. No outcome benefit was evident.[157] Post hoc subgroup analysis indicated that patients younger than 45 years old who arrived at the tertiary care facility with a temperature less than 35°C who were randomly assigned to the cooling limb of the trial did have an improved outcome. A second trial in which more rapid induction of hypothermia was accomplished (35°C by 2.6 hours, 33°C by 4.4 hours) was undertaken. However, the results were similarly negative.[158] Hypothermia has also been evaluated as a neuroprotective strategy in pediatric TBI. The largest randomized controlled trial (RCT) failed to demonstrate improved outcome at 6 months and in fact, demonstrated a trend toward worse outcomes in the hypothermia group.[159]

Based on a lack of demonstrated efficacy in humans, routine use of hypothermia in neurosurgery cannot be advocated in a standard textbook. The decision to use it, usually in the context of aneurysm surgery, is local. The authors continue to use mild hypothermia selectively, most commonly in patients perceived to be at an especially high risk of intraoperative ischemia. If hypothermia is used, cardiac dysrhythmia and coagulation dysfunction can occur if body temperatures become too low. Patients should be rewarmed adequately before emergence to avoid shivering, hypertension, or delayed awakening.

By contrast with clinical neurosurgery, the use of hypothermia after cardiac arrest is now practiced widely. Two multicenter trials demonstrated improved neurologic outcome among survivors of witnessed cardiac arrest cooled to 32 to 34°C within 4 hours and maintained at that temperature for 12 to 24 hours.[160,161] A subsequent randomized trial reported similar outcomes in patients treated with targeted temperature management at either 33°C or 36°C.[162] Widespread clinical application of targeted temperature management has been advocated by an international task force and other groups.[163,164]

Although mild hypothermia is perceived to convey the hazard of coagulation dysfunction and dysrhythmia, neither has been evident in elective neurosurgery in the temperature ranges typically used (32°C-34°C). The issue of where body temperature should be recorded to best reflect brain temperature has been addressed.[165] It appears that esophageal, tympanic membrane, pulmonary arterial, and jugular bulb temperature are all very similar and provide a reasonable reflection of deep brain temperature, whereas bladder temperature does not. During craniotomies, superficial layers of cortex may be substantially cooler than deep brain and central temperatures.

EMERGENCE FROM ANESTHESIA

Most practitioners of neuroanesthesia feel that there is a premium on a smooth emergence—that is, one free of coughing, straining, and arterial hypertension. The avoidance of arterial hypertension is desired because arterial hypertension can contribute to intracranial bleeding and increased edema formation.[166-171] In the face of poor cerebral autoregulation, hypertension also has the potential, through vascular engorgement, to contribute to an increase in ICP. Much of the concern with coughing and straining has a similar basis. The sudden increases in intrathoracic pressure are transmitted to both arteries and veins, producing transient increases in both cerebral arterial and venous pressure, with the same potential consequences: edema formation, bleeding, and elevation of ICP. Coughing is a specific concern with certain individual procedures. In the circumstances of transsphenoidal pituitary surgery in which a surgeon has opened, and subsequently taken pains to close, the arachnoid membrane to prevent CSF leakage, there is a belief that coughing has the potential to disrupt this closure because of the sudden and substantial increases in CSF pressure. Opening a pathway from the intracranial space to the nasal cavity conveys a substantial risk of postoperative meningitis. In other procedures, notably those that have violated the floor of the anterior fossa, air can be driven into the cranium and, in the event of a flap-valve mechanism, cause a tension pneumocephalus. This latter event can only happen when coughing occurs after the endotracheal tube has been removed.

There is a paucity of systematically obtained clinical data to give a perspective to the actual magnitude of the risks associated with emergences that are not considered smooth. Two retrospective studies have revealed that increased postoperative arterial blood pressure was associated with intracerebral bleeding after craniotomy.[170,171] However, whether hypertension occurring at emergence causes postoperative intracerebral bleeding is not clear. Also, the relationship between hypertensive transients at emergence and edema formation is unconfirmed. In anesthetized animals, sudden and very substantial increases in arterial pressure can result in a breach of the BBB with extravasation of tracers.[167] However, there are no data to confirm that the pressure transients associated with the typical coughing episode or common emergence are in fact associated with increased edema formation. Nonetheless, it seems reasonable to take measures, to the extent that these measures do not themselves add potential patient morbidity, to prevent these occurrences.

A common method for the management of systemic hypertension during the last stages of a craniotomy is the expectant and/or reactive administration of lidocaine and vasoactive agents, most commonly labetalol and esmolol.[172] Other drugs, including hydralazine, enalapril, diltiazem, nicardipine, and clevidipine have been used to good effect. Administration of dexmedetomidine during the procedure or just prior to its conclusion also reduces the hypertensive response to emergence[173] and hypertension in the postanesthesia care unit.[174]

There are also many approaches to the prevention of coughing and straining. The authors encourage trainees to include in their anesthetic technique as much narcotic as is consistent with spontaneous ventilation at the conclusion of the procedure, as opioids are antitussive and depress airway reflexes. Patients may also emerge more rapidly and smoothly when the last inhaled anesthetic to be withdrawn is nitrous oxide. This can be supplemented, if necessary, with propofol by either bolus increments or infusion at rates in the range of 12.5 to 25 μg/kg/min.

An additional principle relevant to the emergence from neurosurgical procedures is that emergence should be timed to coincide not with the final suture but rather with the conclusion of the application of the head dressing. Many a good anesthetic for neurosurgery has been spoiled by severe coughing and straining that occurs in association with endotracheal tube motion during the application of the head dressing. Another nuance of our practice has been to withhold administration of neuromuscular antagonists as long as possible in the later stages of the procedure. The administration of lidocaine is another apparently effective technique for reducing airway responsiveness and the likelihood of coughing/straining as the depth of anesthesia is reduced in anticipation of emergence. We commonly administer 1.5 mg/kg of intravenous lidocaine just before the head movement associated with applying the dressing.

Because of the premium placed on minimizing coughing and straining and hypertension, there may be a temptation to extubate from the trachea before complete recovery of consciousness. This may be acceptable in some circumstances. However, it should be undertaken with caution when the circumstances of the surgical procedure make it possible that neurologic events have occurred that will delay recovery of consciousness, or when there may be cranial nerve dysfunction. In these circumstances, it would, in general, be best to wait until the likelihood of the patient's recovery of consciousness is confirmed or until patient cooperation and airway reflexes are likely to have recovered.

BOX 57.8 **Specific Procedures**

- Supratentorial tumors
- Aneurysms and arteriovenous malformations
- Traumatic brain injury
- Posterior fossa procedures
- Transsphenoidal surgery
- Awake craniotomy/seizure surgery
- Stereotactic procedures
- Neuroendoscopic procedures
- Neuroradiologic procedures
- Cerebrospinal fluid shunting procedures
- Pediatric neurosurgery
- Spinal surgery

Specific Procedures

Many of the considerations relevant to individual neurosurgical procedures are generic ones that have already been presented in the preceding section on Recurrent Issues in Neuroanesthesia. The descriptions that follow will highlight only procedure-specific issues (Box 57.8).

SUPRATENTORIAL TUMORS

Craniotomies for excision or biopsy, or both, of supratentorial tumors are among the most common neurosurgical procedures. Gliomas and meningiomas are among the most frequent tumors. The relevant preoperative considerations include the patient's ICP status, and the location and size of the tumor. Location and size of the tumor give the anesthesiologist an indication of the surgical position, the potential for blood loss, and will sometimes reveal a risk of air embolism. VAE is infrequent for the majority of supratentorial tumors. However, lesions (usually convexity meningiomas) that encroach upon the sagittal sinus may convey a substantial risk of VAE. Full VAE precautions, including a right atrial catheter, are usually reserved for only the supratentorial tumors that lie near the posterior half of the superior sagittal sinus.

Excision of craniopharyngiomas and pituitary tumors with suprasellar extension may entail dissection in and around the hypothalamus (see Fig. 57.18). Irritation of the hypothalamus can elicit sympathetic responses including hypertension. Damage to the hypothalamus can result in a spectrum of physiologic disturbances, notably water balance. Diabetes insipidus is the most likely, although the cerebral salt-wasting syndrome can infrequently occur. The various disturbances of water balance typically have a delayed onset, beginning 12 to 48 hours postoperatively, rather than in the operating room. Postoperative temperature homeostasis may also be disturbed.

Patients who undergo a craniotomy involving a subfrontal approach sometimes manifest a disturbance of consciousness in the immediate postoperative period. Retraction and irritation of the inferior surfaces of the frontal lobes can result in a patient who exhibits either delayed emergence or some degree of disinhibition, or both. The phenomenon is more likely to be evident when there has been bilateral frontal lobe retraction. The anesthetic implication is that the clinician should be more inclined to confirm return of consciousness before extubating the patient rather than to extubate expectantly. A further implication taken by these authors (though not confirmed by any systematic study) is that a less liberal use of intravenous anesthetic drugs (e.g., fentanyl, propofol infusion) may be appropriate when there is to be bilateral subfrontal retraction. This is based on the rationale that low residual concentrations of these anesthetics that are compatible with reasonable recovery of consciousness in most patients may be less well tolerated in this population. Subfrontal approaches are most commonly used in patients with olfactory groove meningiomas and patients with suprasellar tumors including craniopharyngiomas and pituitary tumors with suprasellar extension.

Preoperative Preparation

Patients with a significant tumor-related mass effect, especially if there is tumor-related edema, should receive preoperative steroids. A 48-hour course is ideal (see the previous discussion of steroids), although 24 hours is sufficient for a clinical effect to be evident. Dexamethasone is the most commonly used agent. A regimen such as 10 mg intravenously or orally followed by 10 mg every 6 hours is typical. Because of the concern about producing CO_2 retention in patients whose intracranial compliance is already abnormal, sedative premedication outside of the operating room is usually avoided.

Monitoring

Institutional practices vary; however, we almost invariably place arterial catheters for craniotomies under general anesthesia (GA). Preinduction placement may be appropriate in patients with severe mass effect and little residual compensatory latitude. At a minimum, we achieve intra-arterial monitoring before pin placement. It is the period of induction and pinning during which hypertension, with its attendant risks in a patient with impaired compliance and autoregulation, is most likely to occur. Arterial lines also facilitate careful management of blood pressure during emergence. Procedures with a substantial blood loss potential (e.g., tumors encroaching on the sagittal sinus, large vascular tumors) may also justify central venous catheters when peripheral venous access is limited. If not already present for other indications, ICP monitoring is rarely warranted for induction, given our understanding of the potential impact of anesthetics and associated procedures. Once the cranium is open, observation of conditions in the surgical field provides equivalent information.

Management of Anesthesia

The principles governing the choice of anesthetic drugs are presented in the previous section, Control of Intracranial Pressure and Brain Relaxation.

ANEURYSMS AND ARTERIOVENOUS MALFORMATIONS

Contemporary management and current recommendations regarding ruptured intracranial aneurysms call for intervention as early as feasible to reduce the rate of rebleeding.[175] That intervention may entail either operative clipping or an endovascular approach.[175] The latter is discussed in the subsequent section Neurointerventional Procedures.

Early intervention was originally undertaken only in patients in the better neurologic grades—that is, grades I-III and perhaps IV of the World Federation of Neurosurgeons classification (Table 57.2) or grades I-III of the Hunt-Hess classification (Table 57.3)—but is now recommended for the majority of patients.[175] If early intervention is not feasible and a surgical approach is intended, surgery may be delayed for 10 to 14 days to be safely beyond the period of maximal vasospasm risk (i.e., days 4-10 post-SAH).

The rationale for early intervention is several-fold. The sooner the aneurysm is clipped or obliterated, the less the likelihood of rebleeding (and rebleeding is the principal cause of death for patients hospitalized after SAH [176]). Second, the management of the ischemia caused by vasospasm involves fluid resuscitation and induced hypertension. Early occlusion of the aneurysm eliminates the risk of rebleeding associated with this therapy. Prior surgical practices

TABLE 57.3 Hunt-Hess Classification of Neurologic Status After Subarachnoid Hemorrhage

Category	Criteria*
Grade I	Asymptomatic, or minimal headache and slight nuchal rigidity
Grade II	Moderate to severe headache, nuchal rigidity, no deficit other than cranial nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate to severe hemiparesis, possibly early decerebrate rigidity and vegetative disturbances
Grade V	Deep coma, decerebrate rigidity, moribund appearance

*Serious systemic disease, such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography, results in placement of the patient in the next less favorable category.

entailed maintaining the patient on bed rest until approximately day 14, when the period of spasm risk had passed. Early aneurysm clipping reduces the period of hospitalization and reduces the incidence of the medical complications (i.e., deep vein thrombosis, atelectasis, pneumonia) associated with a lengthy period of enforced bed rest.

Early intervention makes the surgeon's task more difficult. The brain in the early post-SAH period is likely to be more edematous than after a 2-week delay. Furthermore, some degree of hydrocephalus is very common after blood contaminates the subarachnoid space. In fact, about 9% to 19% of aneurysmal SAH victims eventually require permanent CSF diversion.[175,177-180] Early intervention may also enhance the risk of intraoperative aneurysmal rupture because of the lesser period of time for a clot to organize over the site of the initial bleed. All this places a substantial premium on techniques designed to reduce the volume of the intracranial contents (see Control of Intracranial Pressure and Brain Relaxation earlier in this chapter) to facilitate exposure and minimize retraction pressures.

Preoperative Evaluation

Many patients scheduled for intracranial aneurysm clipping will come directly from the ICU, and elements of their critical care management may influence their immediate preoperative status.

Intravenous Fluid Management. Some patients develop the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) after SAH and are appropriately managed with fluid restriction. However, hyponatremia after SAH is more likely to be the result of the cerebral salt-wasting syndrome that probably occurs as a result of the release of a natriuretic peptide by the brain.[181,182] Cerebral salt-wasting syndrome is characterized by the triad of hyponatremia, volume contraction, and high urine sodium concentrations (>50 mmol/L), and its occurrence is correlated with the occurrence of symptomatic vasospasm.[183] The distinction between cerebral salt-wasting syndrome and SIADH is important. SIADH, which is characterized by normovolemia or mild hypervolemia, is treated by volume restriction. Cerebral salt-wasting syndrome is associated with a contracted intravascular volume. Fluid restriction and further volume contraction may be especially deleterious in the post-SAH patient and should be avoided.[184-186] Although the clinical distinction between these two causes of hyponatremia (SIADH and cerebral salt-wasting syndrome) may be difficult, management of both is relatively simple: administration of isotonic and/or hypertonic fluids using intravascular normovolemia and normonatremia as the end point.

Vasospasm. The anesthesiologist should determine whether vasospasm has occurred and what, if any, therapies for it have been undertaken. Vasospasm is thought to be caused by the breakdown products of the hemoglobin that have accumulated around the vessels of the circle of Willis after SAH. A specific mechanism/mediator has not been identified. Calcium channels are thought to be involved, and there is also suspicion that the nitric oxide and endothelin systems may be contributory.[186,187]

When there is a clinical suspicion of vasospasm (typically because of a change in sensorium or new neurologic deficit), surgery is usually deferred and TCD, angiography, or other imaging is performed. Symptomatic vasospasm has historically been treated with "Triple H" therapy (hypervolemia, hypertension, and hemodilution). Current management has shifted toward fluid resuscitation to euvolemia (rather than hypervolemia),[175,188] hypertension, and sometimes balloon angioplasty or intraarterial vasodilators.[189]

For patients proceeding to surgery, hypotension should be avoided[175] and CPP should usually be maintained intraoperatively at values near the waking normal range. The association of hypotension with poor outcome,[190] and the potential for hypotension to cause or aggravate cerebral ischemia in patients with some degree of vasospasm, is well recognized.[191-193] This concern should extend even to patients classified as World Federation of Neurosurgeons grade I who may have regions of cerebral ischemia[30] that are subclinical when the patient is normotensive.

In the ICU, the regimens used to treat vasospasm usually involve some combination of fluid resuscitation and blood pressure augmentation. The science behind hypervolemic-hypertensive therapy is soft and the efficacy of neither Triple H therapy nor volume expansion in isolation has been proved by prospective study.[188,194-196] The relative importance of the rheologic and blood pressure effects is undefined, although there is evidence for the relevance of blood pressure elevation in isolation.[187,196-199] Phenylephrine and dopamine are the most commonly used pressors; exact pressor choice should be primarily governed by systemic cardiovascular considerations. The end point for pressor administration varies. Most commonly, the objective is an increase in MAP of approximately 20 to 30 mm Hg above baseline systolic pressure. However, it has been reported that augmentation of cardiac output with dobutamine, without simultaneous MAP increase, augments CBF in ischemic territories.[196] It is also believed that a hematocrit in the low 30s is optimal for cerebral perfusion, but this is not a therapeutic target that is directly manipulated.

Calcium-Channel Blockers. Calcium-channel blockers are an established part of the management of SAH. Administration of nimodipine decreases the incidence of morbidity caused by cerebral ischemia after SAH,[200] although it was not associated with any reduction in the incidence of vasospasm as detected by angiography.[201] Patients presenting to the operating room after SAH should already be receiving nimodipine. Because nimodipine must be administered orally in North America, nicardipine has been evaluated as an intravenous alternative. The multicenter nicardipine trial[202,203] revealed a reduced incidence of symptomatic vasospasm but no improvement in outcome. As a consequence, nimodipine remains the standard. Calcium-channel blockers (i.e., verapamil, nicardipine, nimodipine[204-207]) are also used intraarterially as a primary treatment for medically-refractory vasospasm. Milrinone and papaverine are similarly administered.[206,208]

Other Pharmacologic Therapies. Several other agents/drug classes have been considered for the prevention of vasospasm and delayed ischemic deficits. None of them is approaching the status of standard therapy. A study of the endothelin antagonist clazosentan revealed improved mortality without improvement in the outcome of survivors. After several small trials suggested a beneficial effect of magnesium, a larger randomized, placebo-controlled trial reported no improvement in outcome among patients in whom magnesium was initiated within 4 days of SAH.[209] Several small trials have examined the post-SAH administration of statins. Meta-analysis revealed only nonsignificant trends toward reduced incidence of delayed cerebral ischemia and death.[210] A subsequent large RCT (STASH) failed to demonstrate either short-term or long-term outcome benefits related to statin administration.[211] The phosphodiesterase inhibitor cilostazol (a platelet inhibitor as well as vasodilator) was reported to reduce symptomatic vasospasm,[212,213] new cerebral infarctions,[213] and improve outcome[212] following SAH. Although promising, a larger study to confirm the safety and efficacy of cilostazol is anticipated.

Antifibrinolytics. Antifibrinolytics have been administered in an attempt to reduce the incidence of rebleeding. Although they accomplish this end, long courses do so at the cost of an increased incidence of ischemic symptoms and hydrocephalus, with an overall adverse effect on outcome. However, early, brief courses of antifibrinolytics that are continued until the aneurysm is secured may have a net favorable effect on outcome.[175]

Subarachnoid Hemorrhage-Associated Myocardial Dysfunction. SAH can result in a largely reversible myocardial "stunning" injury. The severity of the dysfunction correlates best with the severity of the neurologic injury [214] and is sometimes sufficient to require pressor support.[215] The mechanism is uncertain but is thought to be catecholamine mediated.[216] Troponin elevation occurs commonly, though typically reaching levels less than the diagnostic threshold for myocardial infarction.[217] Peak troponin levels correlate with the severity of both neurologic injury and echocardiographic myocardial dysfunction.[215,218]

ECG abnormalities are common after SAH. In addition to the classic canyon T waves (Fig. 57.14), nonspecific T-wave changes, Q-T prolongation, ST-segment depression, and U waves have been described. There is typically no relationship between the ECG changes and echocardiographic myocardial dysfunction.[217] ECG abnormalities do not herald evolving or impending cardiac disease.[219] Accordingly, when ventricular function is adequate and ECG patterns other than those that are typical of myocardial ischemia are observed, no specific interventions or modifications of patient management are warranted, other than attention to the possibility of dysrhythmias. In particular, an increased Q-T interval (>550 ms) occurs frequently after SAH, especially in patients with more severe SAH,[218] and has been associated with an increased incidence of malignant ventricular rhythms including torsades de pointes.[220]

Anesthetic Technique

Important considerations include the following:

1. Absolute avoidance of acute hypertension with its attendant risk of rerupture.
2. Achievement of intraoperative brain relaxation to facilitate surgical access to the aneurysm.
3. Maintenance of a high-normal MAP to prevent critical reduction of CBF in recently insulted and now marginally perfused areas of brain, or in regions critically dependent on collateral pathways.
4. Preparedness to perform precise manipulations of MAP as the surgeon attempts to clip the aneurysm or to control bleeding from a ruptured aneurysm or during periods of temporary vascular occlusion.

Monitoring

An arterial line is invariably appropriate. A central venous catheter may be appropriate if peripheral access is inadequate.

Anesthetic Selection. Any technique that permits proper control of MAP is acceptable. However, in the face of increased ICP or a tight surgical field, an inhaled anesthetic technique may be less suitable. The prevention of paroxysmal hypertension is the only absolute requirement in patients undergoing aneurysm clipping. The poorly organized clot over the aneurysms of patients undergoing early post-SAH clipping makes them particularly prone to rebleeding. A rebleed at induction is frequently fatal.[176] The escaping arterial blood is more likely to penetrate brain substance because it cannot dissect through the CSF space (filled with clot), and the ICP increase is extreme because of the poor compliance of the intracranial space (swollen brain, hydrocephalus).

Induced Hypotension. The routine use of induced hypotension has essentially vanished (see previous section Management of Arterial Blood Pressure). Nonetheless, the anesthesiologist should be prepared to reduce blood pressure immediately and precisely if called upon to do so. Preparation of an appropriate hypotensive agent must occur before the episode of bleeding. There are theoretical pros and cons for various hypotensive agents. However, the choice should ultimately be made based on which regimen, in the hands of the individual practitioner, results in the most precise control of MAP. There are rare occasions when the anesthesiologist is asked to control MAP in the range of 40 to 50 mm Hg in the face of active arterial bleeding. This can be extremely difficult in a patient who is hypovolemic at the beginning of the bleeding episode. It is our practice to maintain normovolemia.

Induced Hypertension. Relative hypertension may be requested during periods of temporary arterial occlusion (see the later section Temporary Clipping) to augment collateral CBF. In addition, after clipping of the aneurysm, some surgeons will puncture the dome of the aneurysm to confirm adequate clip placement and may request transient elevation of the systolic pressure to 150 mm Hg. Phenylephrine is suitable in either instance.

Hypocapnia. Hypocapnia has traditionally been used as an adjunct to brain relaxation. However, the practice has been questioned on the basis of the concern that it will aggravate ischemia (see the earlier section Management of $PaCO_2$). It is now generally avoided unless ICP/brain relaxation circumstances demand it.

Lumbar Cerebrospinal Fluid Drainage. CSF drainage has been used to facilitate exposure. However, its use

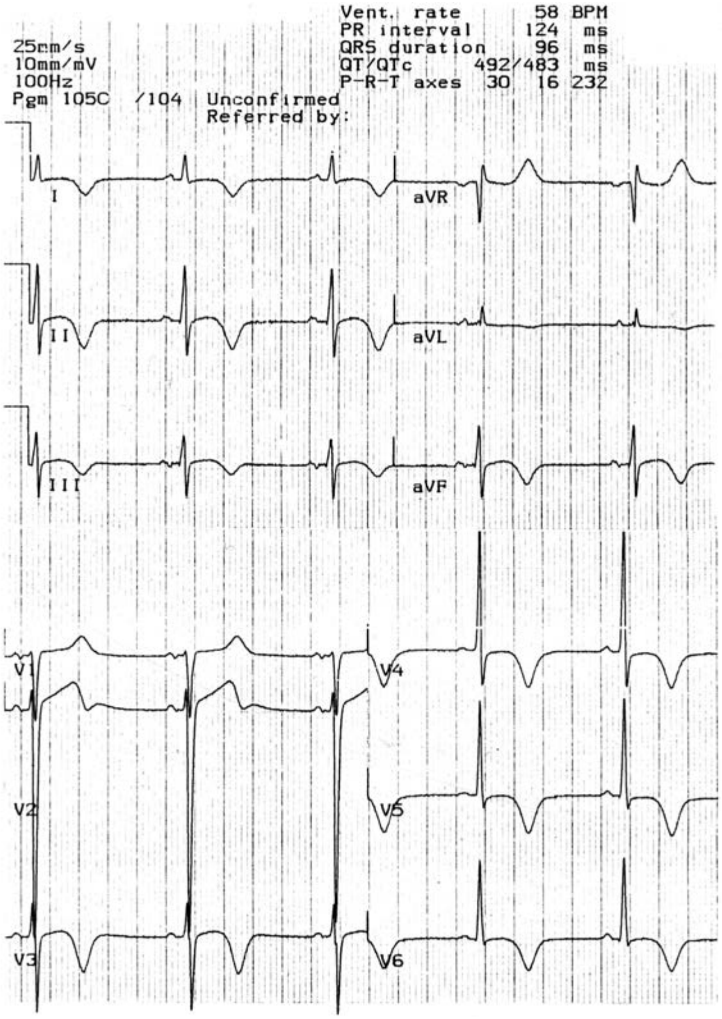

Fig. 57.14 Electrocardiogram abnormalities associated with subarachnoid hemorrhage. The canyon T waves that may be seen after subarachnoid hemorrhage are evident.

appears to be diminishing because surgeons have appreciated that the same brain-relaxing effect can be achieved by release of CSF from the basal cisterns. If a lumbar CSF drain is placed, it is appropriate to avoid excessive loss of CSF. A sudden reduction in the transmural pressure gradient across the dome of the aneurysm (by sudden reduction of ICP consequent upon substantial CSF drainage) should be avoided because of the theoretical concern that this decompression might encourage rebleeding. Having verified the patency of the drainage system, it is usual to leave it closed until the surgeon is opening the dura. The drain is then opened and allowed to drain freely to floor level. Drainage should be discontinued promptly after final withdrawal of the retractors to allow CSF to reaccumulate and to thereby reduce the size of the potential pneumocephalus.

Some surgeons use mannitol relatively aggressively (e.g., 2 g/kg). In part, it is used to facilitate exposure and reduce retractor pressures, but there is evidence that it may have additional benefits. Specifically, there are data derived in both animals and man indicating that mannitol may have a CBF-enhancing effect in regions of moderate CBF reduction.[221-224] The mechanism is not defined. Reduction of interstitial tissue pressure around capillaries and/or an alteration of blood rheology have been proposed as contributors. Typically, mannitol administered in a dose of 1 g/kg just before dural opening provides satisfactory brain relaxation.[45] Surgeons who believe in its CBF-enhancing effect may request a second 1 g/kg approximately 15 minutes before an anticipated temporary occlusion.

Temporary Clipping. Many surgeons limit inflow to an aneurysm during application of the permanent clip by placing a temporary clip proximally on the feeding vessel. It is occasionally necessary to trap the aneurysm (i.e., to temporarily occlude the vessel on both sides of the aneurysm) to complete the dissection of the neck and apply the clip. This is more common with larger aneurysms. With giant aneurysms in the vicinity of the carotid siphon, the inferior occlusion may be performed at the level of the internal carotid artery via a separate incision in the neck. A clinical survey of the neurologic outcome after temporary occlusion in normothermic, normotensive adults revealed that occlusions of fewer than 14 minutes were invariably tolerated. The likelihood of an ischemic injury increased with longer occlusions and reached 100% with occlusions in excess of 31 minutes.[225] In another institution, the threshold for ischemic injury was 20 minutes of occlusion.[226] An informal 7-minute rule is sometimes applied to individual periods of temporary occlusion. Typically, MAP should be sustained at high-normal levels during periods of occlusion to facilitate collateral CBF.

Brain Protection. Maintenance of MAP to ensure collateral flow and perfusion under retractors, efficient brain relaxation to facilitate surgical access and reduce retractor pressures, limitation of the duration of episodes of temporary occlusion, and perhaps mild hypothermia are the important brain protection techniques. Specific anesthetic drugs have been promoted as brain protectants, but evidence is limited (see the discussion in Chapter 11). There have been no convincing laboratory demonstrations that propofol provides any greater tolerance to a standardized ischemic insult than does anesthesia with a volatile anesthetic. Attempts to demonstrate protection by etomidate in an animal model of focal ischemia actually demonstrated an adverse effect of etomidate.[227] Furthermore, a clinical investigation during aneurysm clipping revealed decreases in brain tissue PO_2 in association with administration of etomidate, which contrasted with the brain PO_2 increases that occurred with the introduction of desflurane. During subsequent temporary vessel occlusion, tissue pH decreased alarmingly in patients receiving etomidate and was unchanged with desflurane.[228] Etomidate probably should not be used because of a lack of sufficient data regarding its efficacy. With respect to the volatile anesthetics, attempts in the laboratory to confirm the once proclaimed protective efficacy of isoflurane have demonstrated that there are no differences among the various volatile anesthetics in terms of their influence on outcome after focal or global ischemia in the laboratory.[227,229-231] Nor has there been any demonstration of greater protective efficacy with concentrations of volatile anesthetics sufficient to cause EEG suppression as opposed to more modest (e.g., 1.0 MAC) levels.[231,232] Nonetheless, these animal investigations suggest that a standardized experimental ischemic insult is better tolerated, relative to the awake state, by animals receiving a volatile anesthetic.[230,231,233] In addition, data derived in animals also suggest that there may also be a relative protective advantage to an anesthetic that includes a volatile anesthetic compared with a strict N_2O-narcotic technique. The magnitude of the differences among anesthetics and the absence of proof of relevance in patients precludes advocacy of a particular anesthetic regimen in a standard text. The important anesthetic objectives are precise hemodynamic control and timely wake-up, and those two constraints should dictate the choice of the anesthetic regimen for most aneurysm procedures. Among anesthetics, it is only the barbiturates for which additional protective efficacy has been demonstrated convincingly. Because of their potentially adverse effects on hemodynamics and wake-up, they are not ideal for routine use. They should probably be reserved for situations in which a prolonged vessel occlusion is unavoidable, and in that circumstance, it would be ideal that the ischemic hazard be first confirmed by observation of the EEG response to a temporary occlusion.[234]

The patient with, or at substantial risk for, vasospasm probably benefits from a minimum hemoglobin greater than that which is commonly accepted in stable ICU patients (i.e., >7 g/dL). The best available information suggests a minimal hemoglobin value of 9 g/dL.[199,235]

Hypothermia. As noted in the previous section Hypothermia, a prospective trial of mild hypothermia in patients undergoing aneurysm surgery revealed no improvement in neurologic outcome.[154] Nonetheless, some neurosurgical teams that were already using mild hypothermia (32°C-34°C) are continuing its use for procedures in which temporary vessel occlusion may occur. The institutions that use the lower temperatures are those in which the team is willing to accept a delay in emergence from anesthesia to achieve sufficient rewarming to avoid the extreme hypertension that can occur when a patient is awakened at low body temperatures.

Neurophysiologic Monitoring. Evoked responses and EEG have been used for monitoring.[234,236] EEG monitoring can be used as a guide to management during the period of flow interruption or to guide the administration of CMR-reducing anesthetic agents given before occlusion. At some institutions, the surgeon places an electrode strip over the region of cortex at risk during the intended occlusion. However, the more commonly used skin surface frontal-mastoid derivation is probably sufficient to reveal a major ischemic event. In most circumstances, if occlusion is deemed necessary, a temporary occlusion is performed, and the EEG is observed. If the EEG shows significant slowing, the common practice is to raise the MAP and proceed with as brief as possible a period of occlusion or intermittent episodes of temporary occlusion. If the necessity for a sustained period of occlusion seems likely, it may be appropriate to administer barbiturates (discussed earlier) to produce burst suppression. These events are very infrequent (see also Chapter 39).

Intraoperative Angiography. Intraoperative angiography is an increasingly common component of the management of intracranial aneurysm surgery. It does not have substantial implications for the anesthesiologist except with respect to placement of the radiographic equipment.

Special Considerations for Specific Aneurysms

The most common procedures are performed for aneurysms arising in or close to the circle of Willis. The vessels of origin may be the anterior communicating artery; the middle cerebral artery; the anterior cerebral artery; the ophthalmic artery; the tip of the basilar artery; the posterior communicating artery; and, less frequently, the posterior cerebral artery. These procedures are relatively similar for the anesthesiologist and typically require a supine position with the head turned slightly away from the operative side.

Ophthalmic Artery Aneurysms. Access to the origin of the ophthalmic artery, which is the first intradural branch of the carotid artery, is made difficult by the anterior clinoid process and the optic nerve. As a result, these aneurysms frequently require temporary vascular occlusion. The surgeon commonly first exposes the carotid artery in the neck. When the surgeon reaches the stage of seeking definitive access to the neck of the aneurysm, he or she will occlude first the carotid artery in the neck and then the intracranial portion of the carotid artery immediately proximal to the origin of the posterior communicating artery. A catheter is placed in the excluded segment and put to suction. Blood loss, which is usually minimal, should be monitored.

Vertebrobasilar Aneurysms. These procedures are typically performed in the lateral position. The exposure may involve a combined middle and posterior fossa approach, with some attendant, although minor, risk of VAE. Cortical or skin surface EEG monitoring is of less relevance with vertebrobasilar aneurysms. Auditory, somatosensory, and motor-evoked responses have been used to monitor for vascular compromise.[237-239] As with any other procedure involving the potential for mechanical or vascular injury to the brainstem, cardiovascular responses should be monitored and sudden changes in response to surgical manipulation should prompt immediate notification to the surgeon.[240,241]

Vein of Galen Aneurysms. Vein of Galen aneurysms are congenital dural arteriovenous fistulas, usually treated in the neonate using endovascular methods, and share considerations relevant to AVMs. These include anticipation of the possibility of the cerebral dysautoregulation phenomenon and are considered subsequently.

Arteriovenous Malformations

For the majority of intracranial AVMs, the general considerations are similar to those appropriate to aneurysm surgery: avoidance of acute hypertension and the capability to accurately manipulate arterial blood pressure in the event of bleeding. A problem specific to AVMs is the phenomenon of perfusion pressure breakthrough, or cerebral dysautoregulation.[242,243] It is characterized by an often sudden engorgement and swelling of the brain, sometimes with a relentless cauliflower-like protrusion from the cranium. It tends to occur in the advanced stages of lengthy procedures on large AVMs, or it may be the cause of otherwise unexplained postoperative swelling and hemorrhage. The phenomenon is not entirely understood. An AVM provides a high-volume, low-resistance pathway that chronically diverts blood from adjacent and therefore marginally perfused vascular territories. Perhaps these tissues have long been maximally vasodilated and are incapable of vasoconstricting when exposed to a higher-pressure head after acute obliteration of the AVM. Although this explanation superficially fits the clinical occurrence, experimental data are not entirely consistent with this mechanism.[242-245] At least some component of the hyperemia is not passive, and neurogenic or paracrine mechanisms may be involved.

Anesthetic Technique. The management constraints are essentially the same as those relevant to aneurysm surgery, although the risk of intraoperative rupture is much less. Institutional practices will vary. We do not use induced hypotension unless it is necessitated by bleeding. We reason that the effects on the surrounding brain of devascularizing the AVM would be best appreciated if the devascularization occurs at normal pressures. If refractory brain swelling occurs, tight blood pressure control is essential, and reducing MAP may be of use to control swelling. The latter is based on the notion that CBF through the involved area is pressure-passive and will decrease as MAP is reduced. With severe episodes of swelling, we have used (in addition to hypotension, which we use cautiously because of the associated ischemia risk) hypocapnia, hypothermia, and barbiturates. The latter three techniques probably serve to reduce the bulk of only normal brain tissue, hypocapnia via a direct effect on CBF and barbiturates and hypothermia via the coupled effects of reduction of CMR on CBF. Induced hypothermia is also an adjunct to minimizing the barbiturate doses. In all of neurosurgery, we seek to prevent postoperative hypertension; however, in AVM surgery this should be accomplished with the greatest care because of the concern that the dysautoregulating brain adjacent to the resected AVM will develop edema or hemorrhage if hypertension occurs.

HEAD INJURY

Intubating the Trachea of a Head-Injured Patient

Patients with GCS scores of 7 to 8 (Table 57.4) or less require tracheal intubation and controlled ventilation for ICP or airway control, or both. Patients with less severe TBI may also require intubation because of trauma-related cardiopulmonary dysfunction or, when uncooperative, to facilitate diagnostic procedures. The anesthesiologist, in choosing the intubation technique, may encounter a number of conflicting constraints (Box 57.9). These include: (1) elevated ICP; (2) a full stomach; (3) uncertain cervical spine status; (4) uncertain airway status (e.g., presence of blood, possible laryngotracheal injury, possible skull base fracture); (5) an uncertain volume status; (6) an uncooperative or combative patient; and (7) hypoxemia. The best

BOX 57.9 Factors That May Be Relevant During Intubation of the Head-Injured Patient

- Full stomach
- Uncertain cervical spine stability
- Uncertain airway
  - Blood
  - Airway injury (larynx, cricoarytenoid cartilage)
  - Skull-base fracture
- Uncertain volume status
- Uncooperative/combative
- Hypoxemia
- Increased intracranial pressure

approach is determined by the relative weight of these various factors along with the degree of urgency. The anesthesiologist must not be distracted by placing an excessive initial emphasis on ICP. The anesthesiologist needs to keep sight of the ABCs of resuscitation: securing the airway, guaranteeing gas exchange, and stabilizing the circulation are higher initial priorities than ICP. Do not risk losing the airway or causing severe hypotension for the sake of preventing coughing on the tube or brief hypertension with intubation.

The Cervical Spine

The possibility of causing or aggravating an injury to the cervical spine is a relevant concern. Approximately 2% of blunt trauma victims who reach a hospital, and 8% to 10% of TBI victims with GCS scores less than 8, have a fracture of the cervical spine.[246,247] Those incidences suggest that a hypnotic-relaxant-direct laryngoscopy approach for all patients with a closed head injury might convey a measurable risk of injuring the cervical cord. Nonetheless, although the literature contains contradictions, several published series have concluded that rapid-sequence induction does not convey significant risk of neurologic injury.[248-251] However, it is possible that the incidence of intubation-related neurologic injury is underreported. An informal survey[252] indicated that there have been more such events than one can infer from the published literature.[253,254] Nonetheless, the majority of patients with TBI requiring airway control are intubated using a hypnotic-relaxant-laryngoscopy sequence. In our opinion, the possibility of devastating spinal cord injury may be higher with injuries in the atlanto-occipital region, which are also difficult to identify radiologically, and that the anesthesiologist should identify circumstances in which time latitudes allow more detailed examination or radiologic evaluation. When there is any uncertainty regarding the airway or the cervical spine, direct laryngoscopy (with vigorous atlanto-occipital extension) should probably be avoided when the exigencies of the situation do not require an immediate rapid-sequence induction. The nasal route can be considered if the clinical context warrants it, bearing in mind that risk of infection may be increased with skull base fracture and CSF leak. The anesthesiologist should use discretion (e.g., in the presence of an obvious facial injury, the nasal route should be avoided) and be sensitive to unusual resistance in passing the endotracheal tube.

When a hypnotic-relaxant sequence is used (and the exigencies of airway control will frequently demand it), the standard approach includes the use of cricoid pressure and in-line axial stabilization. In-line traction was once favored but has been supplanted by stabilization because of the perceived risk of overdistraction and cord injury in the event of gross instability. The largest of the clinical series that concluded that oral intubation with anesthesia and relaxation is reasonable[248] used in-line stabilization with the patient's occiput held firmly on the backboard, limiting the amount of "sniff" that was feasible (Fig. 57.15). There is no question that in-line stabilization, properly performed, makes laryngoscopy somewhat more difficult; however, it serves to decrease the amount of atlanto-occipital extension necessary to achieve visualization of the glottis.[255] This is probably because performing the laryngoscopy against the assistant's counterpressure results in greater compression of the soft tissue structures of the tongue and floor of the mouth. Some recommend leaving the back half of the cervical collar in place during laryngoscopy (see Fig. 57.15) because it functions as a strut between the shoulder and the occiput and serves to further limit atlanto-occipital extension.

In a resuscitation situation, before initiating a hypnotic-relaxant sequence, the anesthesiologist should confirm the availability of cricothyrotomy equipment and of someone to make immediate, skilled use of it if necessary. The recently injured brain is very intolerant of hypoxia and hypotension.[256] It is inevitable that there is sometimes failed tracheal intubation. In the extensive experience of the Cowley Shock-Trauma Center in Baltimore, the cricothyrotomy/tracheostomy rate is 0.3%.[257] As is the case in many other situations, the laryngeal mask may be a very useful device for temporizing in the face of a failed intubation and may also provide access for intubation as an alternative to cricothyrotomy.

As noted in Chapter 11, although succinylcholine can cause ICP increases, these increments are small and probably do not occur in patients with serious cerebral injuries.[8]

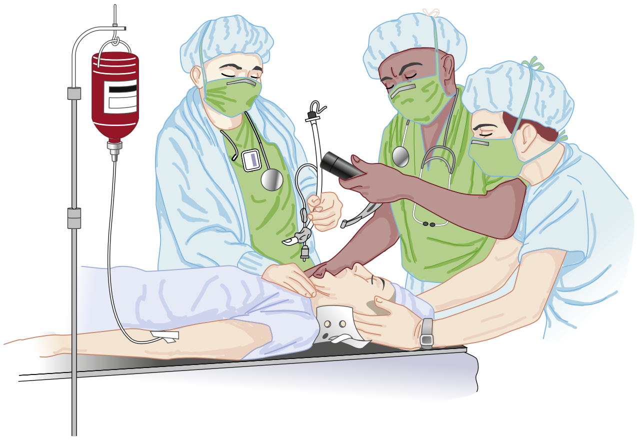

Fig. 57.15 Intubating the acute trauma patient with an uncertain cervical spine. A hypnotic and a relaxant have been administered. One assistant maintains in-line axial stabilization with the occiput held firmly to the backboard; a second applies cricoid pressure. The posterior portion of the cervical collar remains in place to limit atlanto-axial extension. (Reproduced with permission from Stene JD. Anesthesia for the critically ill trauma patient. In: Siegel JH, ed. *Trauma: Emergency Surgery and Critical Care*, Melbourne: Churchill Livingstone; 1987:843–862.)

Accordingly, succinylcholine should not be viewed as contraindicated in the TBI victim. If there is an urgent need to secure the airway (to guarantee oxygenation and control CO_2 tension), and if succinylcholine is in other respects the appropriate drug to achieve that end, it should be used. The necessity to use succinylcholine in these circumstances, however, has diminished with the availability of both rocuronium and the reversal agent sugammadex.

What should the anesthesiologist do with the patient whose cervical spine has not been cleared? That situation should arise with decreasing frequency. The once standard plain radiographs (with their inherent difficulties and substantial false-negative rates) have been supplanted by CT scanners that allow rapid, thin-slice evaluation, with sagittal reconstruction. A large meta-analysis concluded that "modern multislice helical CT alone is sufficient to rule out traumatic, unstable cervical spine injuries."[258] However, some remain concerned that CT may fail to identify ligamentous injuries that would be evident on magnetic resonance imaging (MRI).[259] With respect to a conscious patient who has not yet undergone complete radiologic evaluation, several clinical surveys have confirmed that patients who are alert, not intoxicated, and free of significant distracting injuries invariably have pain, midline tenderness, limitation of voluntary movement, or neurologic signs[260-262] if they have a cervical spine fracture. Despite the frequency with which an anesthesiologist may encounter patients still wearing their cervical collars because their necks have not yet been cleared, no special precautions appear warranted in the asymptomatic, alert patient.

Anesthetic Technique

Choice of Anesthetic Drugs. Craniotomies are most commonly performed for the evacuation of subdural, epidural, or intracerebral hematomas. The anesthetic approach is similar for all three techniques. The guiding principles have been discussed in the section Control of Intracranial Pressure and Brain Relaxation. In general, anesthetics that are known to be cerebral vasoconstrictors are preferable to those that have the potential to dilate the cerebral circulation. All the intravenous anesthetics, except perhaps ketamine, cause some cerebral vasoconstriction and are reasonable choices, provided they are consistent with hemodynamic stability. All the inhaled anesthetics (N_2O and all the volatile anesthetics) have some cerebral vasodilatory effect. Although their administration frequently is consistent with acceptable ICP levels and appropriate conditions in the surgical field, when the ICP is out of control (or unknown), or the surgical field is tight, omitting the inhaled anesthetics in favor of intravenous agents is appropriate. For patients who are likely to remain intubated postoperatively, an anesthetic based primarily on a narcotic, such as fentanyl, and a muscle relaxant usually serves well. Any muscle relaxant is acceptable with the proviso that those that can release histamine (now rarely used) should be titrated in small increments. When immediate tracheal extubation is a possibility (e.g., the patient with an acute epidural hematoma who had a lucid interval before witnessed deterioration), the technique should be modified after the opening of the cranium. Introduction of inhaled anesthetics or the use of shorter-acting intravenous drugs can be undertaken as guided by observation of the surgical field. If N_2O is contemplated at any time, the anesthesiologist must remember the possibility, in the setting of missile injury or compound skull fracture, of intracranial air.

Monitoring. The anesthesiologist should appreciate that the priority is to open the cranium as rapidly as possible.[263] After achieving intravenous access, the risks and benefits of delaying craniotomy for line placement should be considered carefully. An arterial line, often placed after induction in urgent situations, is appropriate for essentially all acute trauma craniotomies. Peripheral venous access is sufficient in the majority of situations. Sudden hypotension after dural opening with high ICP can occur as brainstem compression is relieved.[264] Appropriate intravascular volume resuscitation should mitigate this occurrence. Infrequently, the management of a depressed skull fracture over the sagittal sinus justifies a precordial Doppler and, subject to the surgeon's assessment of VAE risk, a right heart catheter.

Arterial Blood Pressure Management. The concept that the injured brain is extremely vulnerable to what would otherwise be a minor insult (e.g., modest hypotension, moderate hypoxia) has been well confirmed in the laboratory.[265] Although clinically the cause-effect relationships are not absolutely confirmed, several surveys demonstrate the association of otherwise minor degrees of hypotension and hypoxia with poor outcome in both adult[256,266-271] and pediatric patients with TBI.[272] This vulnerability to hypotension probably arises because many patients have brain regions with precariously low CBF in the first 2 to 3 days after TBI[23,26,273-275] and autoregulation is frequently defective.[276-278] The characteristic behavior of CBF after TBI is an initially low CBF followed by a gradual increase over 48 to 72 hours to normal, or sometimes even slightly hyperemic, levels.[23,26,273,274,276,279,280] There is considerable evidence that low post-insult CBF values correlate with a poor eventual outcome,[26,270,275,281-283] and a large percentage of patients who die after TBI have pathologic changes consistent with ischemia.[155] These observations have resulted in a general emphasis among neurosurgeons, neurointensivists, and anesthesiologists on aggressive support of arterial blood pressure in the patient with TBI.

What constitutes an appropriate arterial blood pressure? Systematic studies have revealed that indices of the adequacy of cerebral perfusion derived from $SjvO_2$ and TCD data begin to deteriorate below a mean CPP of 70 mm Hg,[270,284,285] and many centers adopted 70 mm Hg as the CPP target. A clinical investigation comparing the ICU management of patients with TBI at CPPs of 70 and 50 mm Hg demonstrated that, although indices of cerebral well-being were improved by the former, there was no outcome advantage, apparently because of the cardiopulmonary morbidity associated with achieving a sustained CPP of 70 mm Hg.[286] As a result, many authorities have adopted 60 mm Hg as the minimal CPP management objective.[279,287-290] The Brain Trauma Foundation has most recently recommended a CPP target range of 60 to 70 mm Hg in adults.[62] Age-related CPP targets of 40 to 50 mm Hg have been recommended for children.[291]

Maintenance of CPP at 60 to 70 mm Hg in the first 2 to 3 days after TBI is probably reasonable. However, clinicians may encounter other views, including the argument that a one-size-fits-all approach inevitably denies the heterogeneity of pathophysiology among patients with TBI. It is certainly true that not all patients with TBI have low CBF and not all have absent autoregulation. Although an initially low postinjury CBF is probably the most common clinical occurrence, hyperemia does occur.[22,24,280,292,293] It tends to occur in patients with mass lesions rather than contusions, although even those patients have an immediate postinjury period of low CBF, with delayed hyperemia peaking at 24 hours or later.[22,280,282,293,294] Hyperemia may also be more common in children.[295] There is evidence that not all patients with TBI benefit from increases in CPP. Patients with TBI and impaired autoregulation, low baseline flows, increased ICP, and low initial GCS score are most likely to benefit.[296-299] Accordingly, targeted therapy has been advocated.[300-306] However, techniques to discriminate the various flow states (serial CBF measurement, TCD, $SjvO_2$) are not universally available. Some institutions, which have the necessary data analysis capacity, take another approach to targeted therapy. They identify a nominal optimal CPP by examining the changes in ICP that occur in response to variations in MAP. The range of MAPs in which the smallest ΔICP/ΔMAP occurs is taken to be the range within which autoregulation functions most efficiently and is the target range for that individual patient.[301,302] This approach is not feasible in most ICUs. As a result, and despite the theoretic attractiveness of targeted therapy, the CPP target of 60 to 70 mm Hg as an objective is more common.

There are at least two alternative approaches to blood pressure management in patients with TBI (Fig. 57.16). The Lund concept is based on the premises that arterial blood pressure causes hydrostatically driven edema accumulation, and that edema formation can be further aggravated by crystalloid administration and subnormal COP.[307-309] As originally described, the Lund approach in part entailed relative dehydration (furosemide, crystalloid restriction), albumin administration to maintain a normal COP, and the administration of metoprolol and clonidine to lower blood pressure to a CPP target of 50 to 55 mm Hg. At its inception, the approach was controversial because it ran counter to the perceptions of many clinicians of the importance of maintaining a CPP of 70 mm Hg and because of the later demonstration that a negative fluid balance in patients with TBI is deleterious.[271] Over time (and in parallel with a relaxation of the higher CPP targets by others),[279,287,288] the Lund proponents have modified their approach. Normovolemia is now the clinical objective, and CPP is 60 to 70 mm Hg in most patients. The latter has made the approach somewhat less controversial. However, CPP may be reduced to 50 to 60 mm Hg when ICP is not well controlled,[135] and that element remains controversial.[310] Although the proponents of the Lund approach assert improvements in outcome, those reports invariably entail either no control group or comparisons with nonconcurrent controls.[136,311-313] The approach has not been adopted in North America.

The second approach, promoted by neurosurgeons at the University of Alabama at Birmingham (sometimes called the "Rosner concept" after its chief proponent), is that induced hypertension can be used as an adjunct to ICP control.[26,314,315] The underlying concept is that autoregulation is at least partially preserved after TBI and that an increased MAP results in autoregulation-mediated vasoconstriction with a concomitant reduction in CBV and, therefore, ICP. These investigators reported a very satisfactory local experience,[315] but others have reported that induced hypertension was either ineffective or deleterious as a means of reducing increased ICP.[13,316] The Rosner approach now appears to have few advocates.

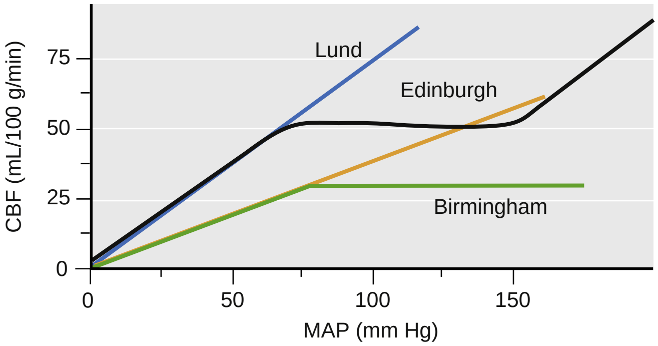

Fig. 57.16 The relationship of cerebral blood flow *(CBF)* to blood pressure after head injury. There are three cerebral perfusion pressure (CPP) management strategies (see text) driven by differing beliefs about common pathophysiologic derangements. The most commonly held strategy is Edinburgh (so named for the institution of the original proponents); it emphasizes low post-injury CBF, impaired autoregulation, and the necessity to support CPP (mean arterial pressure [*MAP*]—intracranial pressure [ICP]) to 60 to 70 mm Hg. The Lund concept emphasizes the contribution of hyperemia to the occurrence of elevated ICP. That approach uses antihypertensive agents to reduce blood pressure while maintaining CPP >50 mm Hg.[307] That CPP target has increased, in the most recent iteration, to 60 to 70 mm Hg, with allowance for occasional reduction to 50 mm Hg.[309] An approach emanating from the University of Alabama, identified as *Birmingham*, entails pharmacologically induced hypertension. That approach is based on the belief that autoregulation is largely intact and that hypertension will result in cerebral vasoconstriction with concomitantly reduced cerebral blood volume and ICP.[314,315]

What should the anesthesiologist managing the patient with TBI do in the face of these various approaches? Perfusion pressure support of varying degrees is a theme that is common to of all of them, and the careful support of CPP at or just above the 60 mm Hg range is probably the most reasonable general approach. When establishing normovolemia alone does not accomplish that objective, phenylephrine, norepinephrine, and dopamine have all been used. With that CPP recommendation offered, it must be acknowledged that convictions vary, and anesthesiologists should come to an understanding with the local traumatologists and neurosurgeons as to CPP targets.

Hyperventilation. The use of hypocapnia has been reviewed in detail in the section Management of $PaCO_2$. The effectiveness of acute hypocapnia in reducing ICP is well confirmed.[13] But there is substantial evidence that hyperventilation is potentially deleterious[20,21,26,29,317,318] and should not be overused. That evidence suggests that hyperventilation and the concomitant vasoconstriction can result in ischemia,[20,21,25,27,317] especially when baseline CBF is low,[27] as is likely to be the case in the first 48 to 72 hours after head injury.[23,24,26,273] The expert panel convened by the Brain Trauma Foundation specified that "prolonged prophylactic hyperventilation with $PaCO_2$ of 25 mm Hg or less is not recommended."[62] Although they did not officially carry forward the recommendations from the third edition, they did restate the following recommendations to convey the concern for vasoconstriction-mediated ischemia: (1) "hyperventilation is recommended as a temporizing measure for the reduction of elevated ICP"; (2) "hyperventilation should be avoided during the first 24 hours after injury when CBF is often critically reduced"; and (3) "if hyperventilation is used, $SjvO_2$ or brain tissue PO_2 measurements are recommended to monitor oxygen delivery."[62] The totality of available information argues that hyperventilation should be used selectively rather than routinely in the management of patients with TBI. Maintaining ICP less than 20 mm Hg, preventing or reversing herniation, minimizing retractor pressure, and facilitating surgical access are still important objectives in the management of the patient with TBI, and to the extent that these objectives cannot be accomplished by other means, hyperventilation may still be appropriate. Once again, the anesthesiologist should agree on management variables with the surgical team at the outset of all procedures.

Intravenous Fluid Management. Intravenous fluid management of the patient with TBI was addressed earlier in the section Intravenous Fluid Management. The important principles are that fluids should be chosen invariably to prevent reduction of serum osmolarity and should probably be chosen to prevent profound reduction of COP—that is, in the circumstances of a large-volume resuscitation (arbitrarily, greater than half of the circulating volume), using a mix of colloids and crystalloids is probably appropriate. The clinical objective should be the maintenance of intravascular normovolemia, in part as an adjunct to MAP and CPP support. A chronic negative fluid balance, as can occur with the combination of modest fluid restriction and liberal use of osmotic diuretics, has been shown to be deleterious and should be avoided.[271] The severely injured brain can liberate sufficient thromboplastin into the circulation to result in a consumptive coagulopathy.[319-321] Appropriate laboratory tests and replacement should be performed. The clinician may also find a serum osmolarity determination early in the course of anesthetic management useful in appreciating the cumulative effects of prior administration of mannitol or HTS. The use of hypertonic solutions and the relevant attributes of colloid solutions were discussed in the section Intravenous Fluid Management. Because of the ischemia that can be a component of TBI, the minimal acceptable hemoglobin level should probably be more than that accepted in stable critical care patients (i.e., 7 g/dL). There is relatively little information to provide guidance. However, one investigation, which presented observations of brain tissue PO_2 ($PbtO_2$), suggested 9 g/dL as a hazard threshold in patients with TBI.[235]

Monitoring

Jugular Venous Oxygen Saturation. $SjvO_2$ monitoring has been used to guide the management of patients with TBI.[20,21,27,28,270,285,286,317,322,323] The underlying concept is that a marginal or inadequate CBF results in an increasing oxygen extraction, a widening arteriovenous content difference, and reduction of $SjvO_2$. Normal subjects have $SjvO_2$ values between 60% and 75%. A $SjvO_2$ less than 50% for 5 minutes is commonly accepted as constituting jugular desaturation. There have been numerous reports of low $SjvO_2$ values improving with interventions including reducing hyperventilation, increasing MAP, or inducing hypervolemia. $SjvO_2$ measurement assesses global oxygen extraction. It might be expected to have limited sensitivity to focal events, and instances in which focal inadequacy of perfusion was not reflected by low $SjvO_2$ have been reported.[20,21,24,317] An additional limitation inherent to the unilateral placement of the catheter is the observation[324] that there is an average side-to-side difference between simultaneous jugular bulb saturations of 5.3 ± 5% and that side-to-side differences in hemoglobin saturation of up to 15% are common.[324]

Despite the reported successes with $SjvO_2$ monitoring,[28,325,326] we do not believe that the method is sufficiently well defined to justify advocating widespread intraoperative application. In the ICU, it appears to be potentially useful as a trend monitor that may serve to identify the level of CPP or hyperventilation below which cerebral perfusion begins to be compromised, with the proviso that there is a significant potential for false-negative results.[20,21,24,317] The technique also has a potential use beyond warning of inadequate perfusion. High $SjvO_2$ values may serve to identify the patient with elevated ICP in whom hyperemia is an important contributing factor and in whom aggressive attempts to decrease CBF (i.e., hyperventilation, barbiturates) may be beneficial.

Brain Tissue PO_2. $PbtO_2$ has been used to guide the management of both TBI and SAH, and there have been limited reports of improvement in outcomes.[316,318-331] A $PbtO_2$ equal to or greater than 20 to 25 mm Hg is viewed as normal, and values equal to or less than 10 to 15 mm Hg are assumed to convey a substantial risk of hypoxic injury. One investigation reported that 29% of patients with TBI with GCS scores of 8 or less have brain regions with $PbtO_2$ less than 10 mm Hg, despite meeting CPP and ICP targets of 60 mm Hg or less than 25 mm Hg, respectively.[289] This would seem to encourage the use of these monitors. However, $PbtO_2$ monitors suffer from the inverse of the problem that prevails with $SjvO_2$ monitoring: they provide very focal information about the oxygenation status of only small regions of brain surrounding the tip. If they are placed remotely from focal injuries to provide a global measure of oxygenation, they may not see adverse events in at-risk but salvageable perilesional tissue.[332] They may similarly fail to be a useful therapeutic guide if they are within irredeemably injured brain. The use of $PbtO_2$ monitoring is neither standardized nor widespread.

Intracranial Pressure Monitoring for Nonneurologic Surgery in the Brain-Injured Patient. The relevant variables when nonneurologic surgery is considered for the brain-injured patients include:

1. *The level of consciousness.* If there has been a loss of consciousness at any time (or amnesia for the event in the absence of witnesses) or if the GCS score is less than 15, a CT scan should be obtained. If the CT scan reveals compressed basal cisterns (indicative of an exhaustion of supratentorial compensatory latitudes), midline shift, or effaced ventricles, and probably any intracranial lesion (e.g., contusion, small subdural), an ICP monitor should be considered for surgery, with GA performed within 48

hours after TBI. Excessive comfort should not be taken from a good GCS score. Patients with good scores can talk and deteriorate or talk and die after a TBI associated with loss of consciousness. Delayed deterioration has been observed as much as 4 days after the initial injury.[333,334] Patients with lesions, usually contusions, in the frontal and frontotemporal region, and especially those with medial temporal lesions, are most at risk for this phenomenon. Modest expansion of lesions in this location (i.e., close to the uncus and the incisura where herniation occurs) can result in herniation even at relatively low ICPs (e.g., ≈20 mm Hg). At our institution, neurosurgeons would recommend avoiding an anesthetic in these patients and would certainly advise ICP monitoring if lengthy GA were unavoidable.

2 *Time since injury.* The longer the patient has had to declare his or her clinical course, the less pressing is the need for ICP monitoring. Delayed deterioration has been observed after as much as 48 hours,[333] and 4.5 days in separate investigations,[334] and a patient with a demonstrable CT lesion and a GCS score less than 15 is a candidate for a monitor during this time frame.
3. *Nature and duration of the intended procedure.* The risks of an untoward ICP event are inevitably greater in a 6-hour spine instrumentation in the prone position than in a 20-minute debridement and suturing of an arm laceration.

Hypothermia

There is clearly an ischemic component to the pathophysiology of TBI, and mild induced hypothermia has been shown to be highly protective in experimental cerebral ischemia. On that basis, the study of hypothermia after experimental TBI was undertaken, and improvements in outcome were demonstrated.[156] Several local, prospective trials of hypothermia after TBI were performed.[335-338] Because those trials appeared to indicate good patient tolerance of sustained mild hypothermia (32°C-34°C) and improvement in ICP and outcome, a multicenter trial was performed. That trial, which required induction of hypothermia within 8 hours of injury, revealed no overall benefit.[157] Because of concern that 8 hours was not sufficiently rapid, a second trial, which achieved the target temperature in 2.5 hours, was performed. It too was negative for benefits.[158] A recent European multicenter trial (EUROTHERM) evaluated hypothermia plus standard care versus standard care alone and failed to demonstrate an outcome benefit of hypothermia.[339] (Also see the section Hypothermia.) As a result, there is no established role for hypothermia in TBI management as of this writing.

POSTERIOR FOSSA PROCEDURES

TABLE 57.5 Considerations Relevant to Posterior Fossa Procedures and the Location of the Related Discussion in This Chapter

Consideration	Chapter Section, Subsection
Hemodynamic effects of the sitting position	Positioning, Sitting
Venous air embolism	Venous Air Embolism
Paradoxical air embolism	Venous Air Embolism
Hemodynamic effects of brainstem and cranial nerve manipulation	Posterior Fossa Procedures
Macroglossia	Positioning, Sitting
Pneumocephalus	Pneumocephalus
Quadriplegia	Positioning, Sitting

Most of the topics relevant to posterior fossa procedures (Table 57.5) have been discussed in the section Recurrent Issues in Neuroanesthesia. These include the sitting position and its cardiovascular effects and complications (quadriplegia, macroglossia), pneumocephalus, and VAE and PAE. The use of the sitting position to facilitate surgery in the posterior fossa increases the likelihood of all these phenomena, though they are relevant to nonsitting positions as well. This section reviews the cardiovascular events associated with direct stimulation of the brainstem and their possible implications for postoperative management.

Brainstem Stimulation

Irritation of the lower portion of the pons and the upper medulla (Fig. 57.17) and of the extra-axial portion of the fifth cranial nerve can result in a number of cardiovascular responses. The former two areas are most often stimulated during procedures on the floor of the fourth ventricle and the last during surgery at or near the cerebellopontine angle (e.g., acoustic neuromas, microvascular decompression of fifth [tic douloureux], seventh [hemifacial spasm], or ninth [glossopharyngeal neuralgia] cranial nerves). The responses may include bradycardia and hypotension, tachycardia and hypertension, or bradycardia and hypertension, and ventricular dysrhythmias.[340] Meticulous attention to the ECG and a directly transduced arterial pressure during manipulation in this region are necessary to provide the surgeon with immediate warning of the risk of damage to the adjacent cranial nerve nuclei and respiratory centers. Pharmacologic treatment of the dysrhythmias that occur may serve to attenuate the very warning signs that should be sought.

Irritation and injury of posterior fossa structures that may have occurred during surgery should be considered in planning extubation and postoperative care. In particular, procedures involving dissection on the floor of the fourth ventricle entail the possibility of injury to cranial nerve nuclei or postoperative swelling in that region, or both. Cranial nerve dysfunction, particularly of nerves IX, X, and XII, can result in loss of control and patency of the upper airway, and swelling of the brainstem can result in impairment of both cranial nerve function and respiratory drive. The posterior fossa is a relatively small space, and its compensatory latitudes are even more limited than those of the supratentorial space. Relatively little swelling can result in disorders of consciousness, respiratory drive, and cardiomotor function. There should be an interaction between the anesthesiologist and the surgeon in deciding whether extubation is appropriate and where postoperative observation should occur (i.e., ICU or non-ICU).

Spontaneous ventilation was once advocated for procedures that entailed a risk of damage to the respiratory centers.[341] Spontaneous ventilation is now rarely used because

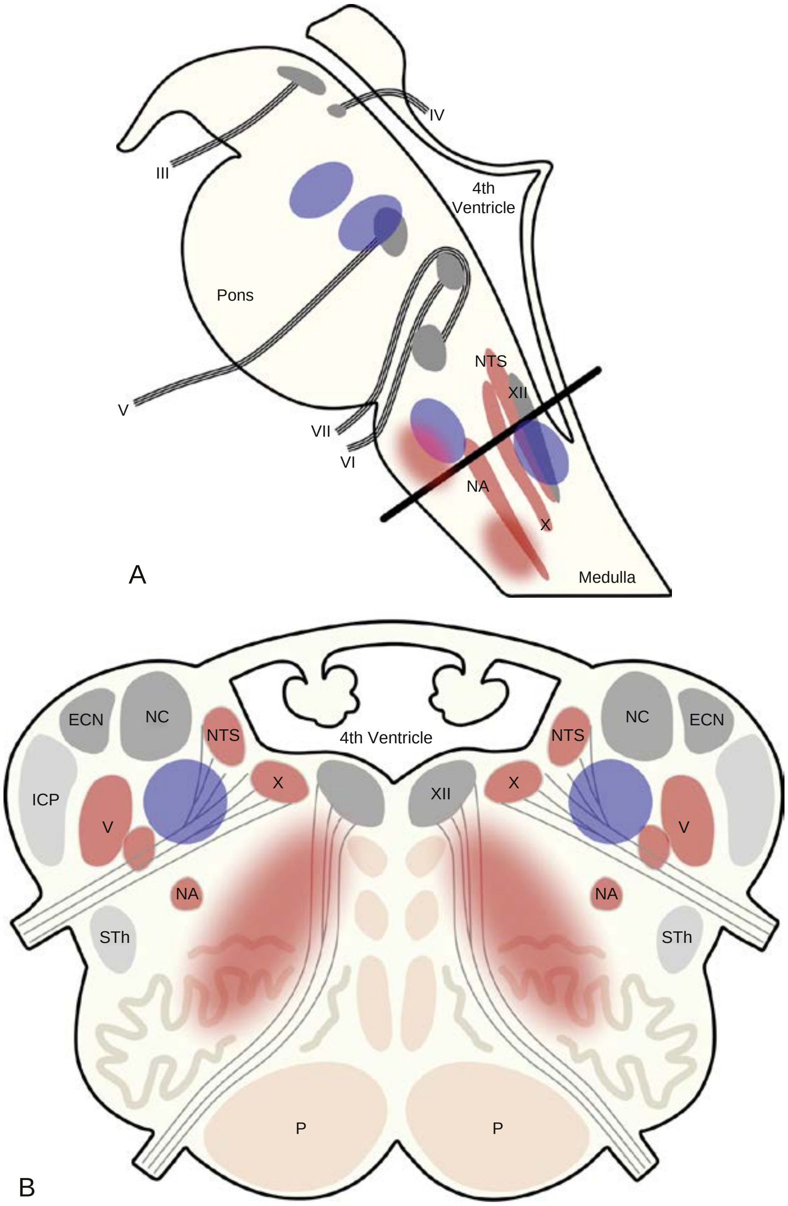

Fig. 57.17 Vasomotor and respiratory centers. Sagittal (A) and axial (B) illustrations of vasomotor centers *(red)* and respiratory centers *(blue)* located near the floor of the 4th ventricle. Minor brainstem manipulation resulting in stimulation of structures in red can lead to significant cardiovascular responses including hypertension, hypotension, bradycardia, and tachycardia. *ECN*, External cuneate nucleus; *ICP*, inferior cerebellar peduncle; *NA*, nucleus ambiguous; *NC*, nucleus cuneatus; *NTS*, nucleus tractus solitarius; *P*, pyramid; *STh*, spinal thalamic tract; *V*, spinal nucleus and tract of trigeminal nerve; *X*, dorsal motor nucleus of vagal nerve; *XII*, hypoglossal nerve nucleus.

the proximity of the cardiovascular and respiratory centers should permit cardiovascular signs to serve as an indicator of impending injury to the latter. Furthermore, electrophysiologic monitoring as a means of detecting brainstem injury has largely supplanted the role of spontaneous ventilation.[341]

Various electrophysiologic monitoring techniques may be used during posterior fossa surgery. These include somatosensory evoked and motor evoked potentials (SSEPs, MEPs), brainstem auditory evoked responses, and electromyographic (EMG) monitoring of lower cranial nerves. MEPs and EMG monitoring require that the patient not be paralyzed or have a constant state of incomplete paralysis. SSEPs and MEPs impose some constraints with respect to the selection of anesthetics. These are discussed in Chapter 39.

Balloon Compression of the Trigeminal Ganglion

This is another situation in which a dysrhythmia may occur. The procedure attempts to produce a neuropraxia of the fifth cranial nerve by the rapid inflation of a Fogarty-type balloon within Meckel's cave.[342,343] The balloon is introduced percutaneously through the cheek and beneath the maxilla. The procedure is best accomplished with a general anesthetic because both the entry of the needle into Meckel's cave and the balloon compression (lasting several minutes) are intensely stimulating. A relatively profound, although transient, bradycardia occurs and is sought as confirmation

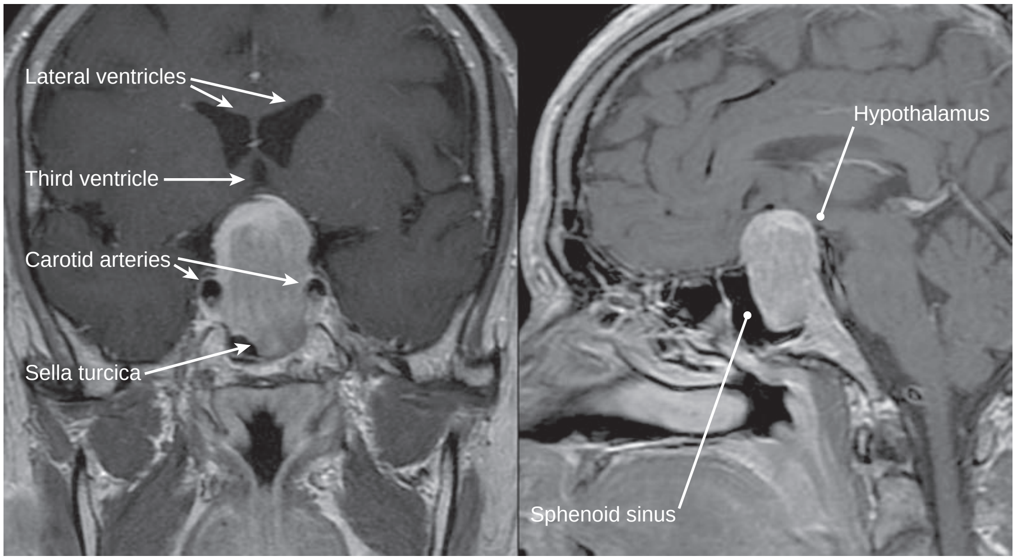

Fig. 57.18 Pituitary tumor with suprasellar extension. The *left panel* shows the proximity of the tumor to the carotid arteries (which lie within the cavernous sinuses) and the potential for distortion of the ventricular system. The optic chiasm (not seen) lies above the sella in the path of the upwardly expanding tumor. The *right panel* shows that tumors that lie above the sella (including craniopharyngiomas, which arise in this location) abut and can invade the hypothalamus. The more radio-dense *(whiter)* cap over the superior and anatomic right lateral aspects of the tumor mass is a normal pituitary gland.

of adequate compression. External pacemaker pads have been advocated but in our experience are unnecessary.

TRANSSPHENOIDAL SURGERY

The transsphenoidal approach to the sella turcica is used for the excision of tumors that lie within the sella or its environs (Fig. 57.18). Most of these lesions are tumors arising from the pituitary gland, and the most common of these are prolactin-secreting microadenomas and nonsecreting macroadenomas. Patients with the former are usually women who present with secondary amenorrhea or galactorrhea, or both. The nonsecreting adenomas tend to manifest with mass effects (headache, visual disturbance, hypopituitarism) and are typically larger at the time of diagnosis. Patients may also present with hypopituitary states as a result of dysfunction of the normal gland caused by compression by the tumor mass. There are three other less common pituitary tumors: growth hormone-secreting lesions, which result in acromegaly; adrenocorticotropic hormone (ACTH)-secreting tumors, which cause Cushing disease; and a very rare thyroid-stimulating hormone-secreting lesion, which results in hyperthyroidism. A detailed review of the perioperative management of this group of patients is available.[344]

Preoperative Evaluation

The important preoperative considerations relate to the patient's endocrine and visual status. In general, as a pituitary lesion expands and compresses the pituitary tissue, normal glandular function is compromised. Hormonal function is lost in the following sequence: first, gonadotrophins; second, growth hormone; third, ACTH; and fourth and last, thyroid-stimulating hormone. A decrease in ACTH secretion results in a hypoadrenal state. Attention to this is critical because an Addisonian crisis can ensue, especially under the stress of surgery. Profound hypocortisolism, with associated hyponatremia, should be corrected preoperatively. Deficiency in thyroid function is uncommon. However, if significant hypothyroidism is present, it should be corrected preoperatively because hypothyroid patients have a diminished tolerance to the cardiovascular depressant effects of anesthetics. Attention to other manifestations of pituitary hypersecretion is also important. Hypertension, diabetes, obstructive sleep apnea (OSA), and central obesity are common concomitants of ACTH-secreting adenomas (Cushing disease). Patients with advanced acromegaly can develop an enlarged tongue and a narrowed glottis, and the airway should be evaluated accordingly. The dermis is thickened, and vascular cannulation can be more difficult. Hypertension, OSA, and a cardiomyopathy may also occur.

Monitoring

Many practitioners place an arterial catheter, and this facilitates monitoring of blood pressure as the nasal mucosa is injected with epinephrine-containing local anesthetic solutions. Access for blood sampling is also a useful adjunct to postoperative care if diabetes insipidus develops. Blood loss is usually modest. However, the cavernous sinuses, through which the carotid arteries pass (see Fig. 57.18), form the lateral boundary of the sella and may be entered during the resection of large tumors. Entry into these structures can lead to catastrophic blood loss. In addition, in some patients there is an extensive venous sinus connecting the two cavernous sinuses that may cover the entire dural lining of the sella, rendering a transsphenoidal approach hazardous. It has, on occasion, actually precluded this approach to the pituitary gland.

Anesthetic Technique

The latitudes are broad with respect to choice of agent, although tumors with suprasellar extension (see Fig. 57.18) can occasionally cause hydrocephalus and add increased ICP constraints to the anesthetic technique. The procedure is performed in the supine position, usually with some degree of head-up posture to avoid venous engorgement. A pharyngeal pack prevents the accumulation of blood in the stomach (which causes vomiting) or in the glottis (which contributes to coughing at extubation). A right-angle endotracheal (RAE)-type endotracheal tube secured to the lower jaw at the corner of the mouth opposite the surgeon's dominant hand (e.g., the left corner of mouth for a right-handed surgeon) is suitable. A small esophageal stethoscope and temperature probe can lie with the endotracheal tube.

The procedure is commonly performed with a C-arm image intensifier (lateral views), and the head and arms are relatively inaccessible once the patient is draped. It is appropriate to establish the nerve stimulator at a lower extremity site. The surgical approach is via the nasal cavity, usually through an incision made under the upper lip or via the nares. During the approach, the mucosal surfaces within the nose are infiltrated with a local anesthetic and epinephrine solution, and the patient should be observed for the occurrence of dysrhythmias.

Surgical preferences for CO_2 management vary. In some instances, hypocapnia is requested to reduce brain volume and minimize the degree to which the arachnoid bulges into the sella. One of the important surgical considerations is the avoidance, when possible, of opening the arachnoid membrane leading to leakage of CSF. Postoperative CSF leaks can be persistent and are associated with a considerable risk of meningitis. By contrast, when there is suprasellar extension of a tumor, a normal CO_2 level helps deliver the lesion into the sella for excision.[345] As an alternative method to accomplish this, some surgeons have resorted to boluses of saline into the lumbar CSF space.[346]

A smooth emergence (see the section Emergence from Anesthesia) from anesthesia is desirable, especially if the CSF space has been opened (and resealed with fibrin glue or by packing the sphenoid sinus with fat or muscle). Repeated intense Valsalva maneuvers, as with coughing or vomiting, may contribute to the reopening of a CSF leak and worsen the risk of subsequent meningitis. The airway should be cleared of debris including formed clots. In situations in which there is concern that a persistent CSF leak may occur, the surgeon may place a lumbar CSF drain to maintain CSF decompression in the early postoperative period.

Diabetes Insipidus

The antidiuretic hormone (ADH) is synthesized in the supraoptic nuclei of the hypothalamus and is transported down the supraoptic-hypophyseal tract to the posterior lobe of the pituitary gland. This portion of the pituitary gland is frequently spared during transsphenoidal tumor excisions. Even when it is excised, water homeostasis commonly normalizes, presumably because the ADH is released from the cut end of the tract. When the pituitary stalk is transected, and sometimes even when the posterior lobe of the pituitary gland is left intact, transient diabetes insipidus may occur. Diabetes insipidus very rarely arises intraoperatively; it usually occurs 12 to 48 hours postoperatively. The clinical picture is one of polyuria in association with a rising serum osmolality. The diagnosis is made by comparison of the osmolality of urine and serum. Hypoosmolar urine in the face of an elevated and rising serum osmolality strongly supports the diagnosis. In the presence of bona fide diabetes insipidus, urine-specific gravity is low (i.e., ≤1.002), though this analysis is now rarely performed.

When the diagnosis of diabetes insipidus is established, the following fluid management regimen is appropriate: hourly maintenance of fluids plus two thirds of the previous hour's urine output. (An acceptable alternative is the previous hour's urine output - 50 mL + maintenance.) The choice of fluid is dictated by the patient's electrolyte levels. In general, the patient is losing fluid that is hypoosmolar and relatively low in sodium. Half-normal saline and 5% dextrose in water are commonly used as replacement fluids. Beware of hyperglycemia when large volumes of 5% dextrose in water are used. If the hourly requirement exceeds 350 to 400 mL, desmopressin acetate is often administered.

AWAKE CRANIOTOMY AND SEIZURE SURGERY

Awake craniotomies are performed when tumors or epileptic foci lie close to cortical areas required for either speech or motor function, or to mesial-temporal structures critical to short-term memory. Many patients have so-called temporal lobe epilepsy. There is commonly a structural lesion visible on MRI. Sometimes there is a history of remote trauma.

Presurgical Evaluation

Before the resection, most patients have undergone a Wada test, video-telemetry, or both.[347] More recently, functional testing using MRI or positron emission tomography, or both, has also been introduced to the presurgical evaluation. The Wada test involves selectively anesthetizing the cerebral hemispheres, usually by injection of amobarbital sodium into the carotid artery to localize the hemisphere that controls speech or to confirm that there is bilateral representation for short-term memory, or both. Speech is an issue when the posterolateral portions of the temporal lobe are involved, and memory is the concern when the involvement is mesial.

Anesthesia for Electroencephalogram Electrode Placement

Video-telemetry is performed to permit localization of the seizure focus that is responsible for the clinically problematic events. This usually requires prior placement of either subdural strip electrodes (via burr holes) or a subdural electrode grid (requiring a craniotomy). Electrodes are sometimes placed deep into the parenchyma, usually within the temporal lobe (placed stereotactically via burr holes), or they are positioned to look at the inferior surfaces of the temporal lobe. The latter is commonly accomplished with so-called foramen ovale electrodes. These electrodes are placed using a needle similar to an epidural needle. The point of entry is approximately 2 cm lateral to the angle of the mouth. The needle is passed through soft tissue, under the temporal process of the zygomatic bone and medial to the ramus of the mandible, up to the base of the skull in the vicinity of the foramen ovale. Typically, this procedure is performed with monitored anesthesia care (MAC) only, although small doses of anesthetics, most often propofol, are usually required at the time of stimulation by the needle of the periosteum at the base of the skull. After placement of the relevant electrodes, the patient's seizure medication is discontinued, and the patient remains in an observation unit with EEG and behavior recorded continuously. In this manner, the EEG events associated with the clinically significant seizure events and their anatomic origin can be identified.

Preanesthetic Evaluation and Preparation

At the preoperative interview, the patient should be educated about the nature and duration of the procedure and the limitations on patient movement. A description of both the aura and the seizures to facilitate recognition of impending events should be obtained, and it should be ascertained whether the patient is subject to having grand mal convulsions. If intraoperative electrocorticography to identify seizure foci is intended, it is common to discontinue or reduce by half the anticonvulsants according to the perceived risk of uncontrolled seizures. Premedicants with an anticonvulsant effect (e.g., benzodiazepines) should not be used because they may interfere with intraoperative EEG localization.

Anesthetic Technique

The objectives of the anesthetic technique are as follows:

1. To minimize patient discomfort associated with the potentially painful portions of the procedure and with the prolonged restriction of movement.
2. To ensure patient responsiveness and compliance during the phases of the procedure that require assessment of speech, memory, or motor/sensory responses to cortical stimulation.
3. To select anesthetic techniques that produce minimal inhibition of spontaneous seizure activity.

There are probably many ways of providing sedation that are consistent with the objectives just cited. The techniques used range from minimal sedation approaches, through deep sedation during which intermittent unresponsiveness is achieved with spontaneous ventilation and an unprotected airway, to asleep-awake-asleep techniques with intermittent airway management with a laryngeal mask airway (LMA) or endotracheal tube, sometimes with positive-pressure ventilation. From the outset, the anesthesiologist should appreciate that the essential element of an anesthetic for an awake craniotomy is the local anesthetic technique. Sedation cannot compensate for inadequate anesthesia of the scalp, as is accomplished by nerve blocks (Fig. 57.19), and pin site infiltration. Although the anesthesiologist can contribute enormously to the patient's comfort and tolerance of the painful components of the procedure and the prolonged immobilization, the anesthesiologist must not get trapped into thinking that it is his or her responsibility to provide a general anesthetic equivalent in a spontaneously breathing patient with an unprotected and all but inaccessible airway.

For sedation, there are many options. Many clinicians (including the authors) use principally propofol,[348,349] sometimes supplemented with infusion of remifentanil (e.g., 0.02-0.05 μg/kg/min) or dexmedetomidine (e.g., 0.2 μg/kg/h). Other combinations, including propofol with either fentanyl or remifentanil and dexmedetomidine with or without remifentanil, are reasonable.[350-352] Great care should be taken in administering additional sedative drugs, especially narcotics whose respiratory depressant effects will be synergistic with propofol. This is especially relevant in the presence of pin fixation, which severely restricts the anesthesiologist's capacity to intervene quickly in the event of excessive respiratory depression or loss of patency of the airway. Propofol should be discontinued at least 15 minutes before EEG recording. Despite prompt awakening, propofol leaves a residual EEG footprint characterized by high-frequency, high-amplitude β activity that can obscure the abnormal activity that is being sought in the cortical surface EEG.[348] The use of dexmedetomidine, which in addition to sedation and anxiolysis provides some analgesia with minimal respiratory depression, is increasing.[352-356] Satisfactory conditions for functional testing, including brain stimulation for speech mapping and electrocorticography, have been reported with dexmedetomidine infusions ongoing at rates between 0.1 and 0.5 μg/kg/h during the testing.[352,354,357,358] The occurrence of delays in achieving satisfactory patient responsiveness has also been reported,[355,359] and using only relatively modest infusion rates (i.e., 0.1-0.2 μg/kg/h) during neurocognitive testing appears advisable.[357] Administration of antiemetics (ondansetron or dexamethasone, or both) should probably be routine, especially if narcotics are administered.

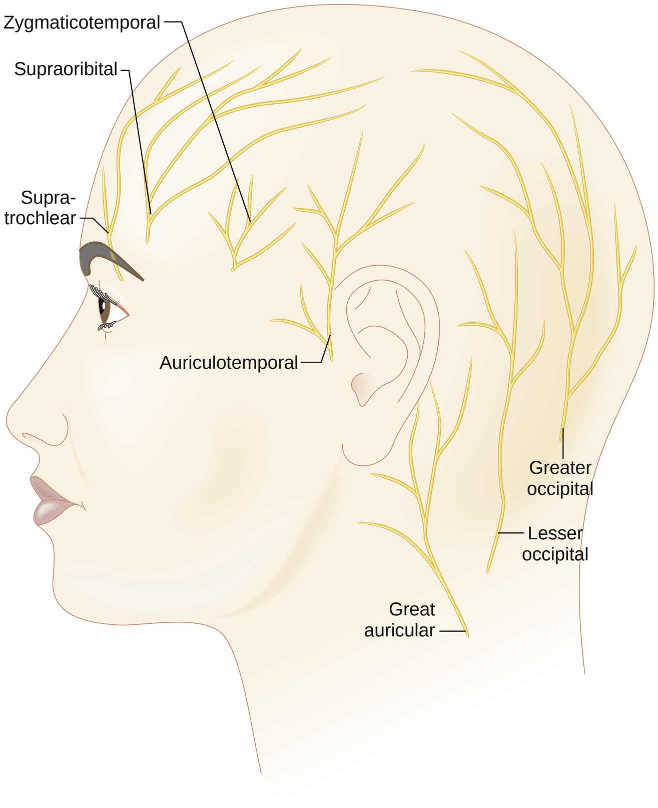

Fig. 57.19 The cutaneous nerves of the scalp.

Various groups have reported the use of the LMA with either spontaneous or controlled ventilation during the craniotomy, with cessation of sedative administration and LMA removal once the brain surface is exposed.[353-355,357,360,361] It is obvious that many approaches can be effective, but it should be noted, for the most part, that the LMA techniques have been used in patients who were *not* in pin fixation of the head. An awake-asleep-awake technique using insertion, removal, and replacement of an endotracheal tube has been reported, but a customized tube that allows installation of local anesthetic in the glottis and trachea was used.[362]

Routine, noninvasive monitors are almost always sufficient. Reliable capnography, to provide breath-by-breath confirmation of airway patency and respiratory drive, is essential if deep sedation is intended for any portion of the procedure. These procedures are often lengthy. Attention to the details of patient comfort (temperature management, padding of pressure areas) improve patient tolerance.

The uncomfortable phases of the procedure are pin head holder placement (not all groups use a pin head holder) and the craniotomy. Many patients also find manipulation of the dura, in particular, traction on subtemporal dura, painful. The actual manipulation of supratentorial brain parenchyma is painless. The volume of local anesthetic used to infiltrate pin sites and perform the scalp nerve blocks can be substantial. It is appropriate for the anesthesiologist to keep track of, and provide advice about, the doses of local anesthetics used.

The anesthesiologist should participate actively at the time of head positioning. The more neck flexion and atlanto-occipital extension that can be achieved before the final lockdown of the head holder, the wider the latitudes will be for sedating the patient, while maintaining spontaneous ventilation and a patent airway. During positioning of the patient, there should also be attention to the need to maintain visual access to the face. A clear line of sight to the face is necessary to present the patient with images to name as part of speech testing and to identify the occurrence of facial motor responses during mapping of the motor strip.

In general, after the dural opening is complete, for seizure-related resections, cortical surface EEG recording is performed to locate the seizure focus. If no seizure activity is observed, provocative maneuvers may be requested.[363] Methohexital in a dose of approximately 0.3 mg/kg is generally safe and effective. Etomidate, approximately 0.05 to 0.1 mg/kg, has also been used. Localization of seizure focus can also be accomplished during light GA (e.g., N_2O /fentanyl/ low-dose isoflurane). During GA, alfentanil, in a bolus dose of 30 to 50 µg/kg[364,365]; etomidate in doses of 0.2 to 0.3 mg/kg[366,367]; and remifentanil, as a bolus of 2.5 µg/kg[368] have been reported to be effective in activating seizure foci. Hyperventilation may also help activate seizure foci.[369]

After localization by EEG (or initially in nonseizure-related resections), functional testing is performed by electrical stimulation of the cortical surface with observation for motor, sensory, or speech interruption effects. During cortical stimulation, the anesthesiologist should be prepared to treat grand mal convulsions. Seizures usually stop with cessation of stimulus or with irrigation of the cortex with cold saline. When they are not self-limited, pharmacologic intervention (e.g., with propofol in increments of 0.5-1.0 mg/kg) may be warranted. However, propofol should be withheld briefly until it is clear that the seizure is not going to terminate spontaneously because it may interfere with subsequent EEG localization for some time.[348]

STEREOTACTIC PROCEDURES

Stereotactically guided procedures are performed for numerous indications including biopsy of small, deep-seated lesions and placement of deep brain stimulation electrodes.

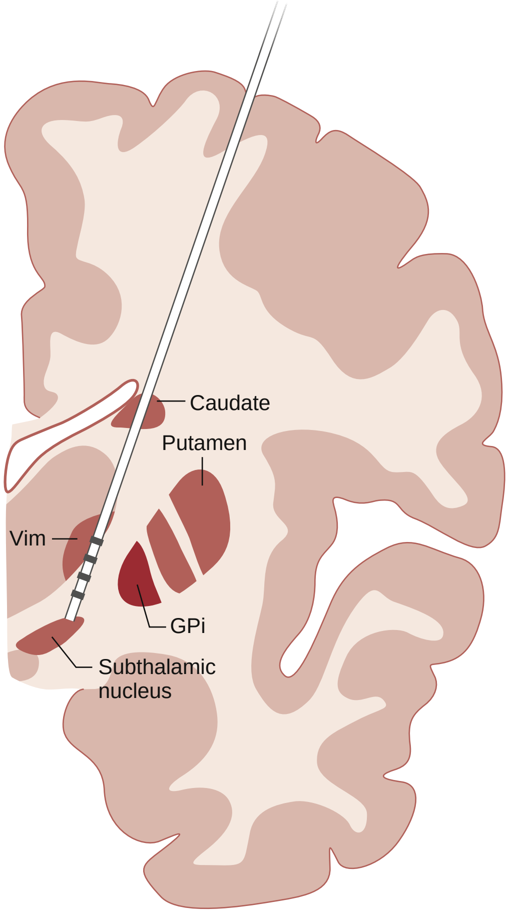

Fig. 57.20 Deep-brain stimulation electrode target sites. The most commonly targeted nuclei for the treatment of movement disorders are the subthalamic nucleus, the ventral intermediate nucleus of thalamus *(Vim)*, and the internal segment of globus pallidus *(GPi)*.

The latter are placed most commonly for the treatment of movement disorders (Parkinson disease, essential tremor, and dystonias)[370] and sometimes for a variety of other conditions (Tourette disorder, obsessive-compulsive disorder, and depression). Procedures related to movement disorders most often target the subthalamic nucleus, the internal segment of the globus pallidus, or the ventral intermediate nucleus of the thalamus (Fig. 57.20).[370] The mechanism of the beneficial effect of deep brain stimulation is not well understood. A prominent theory is that the abnormal motor patterns are caused by synchronized oscillations in neural circuits involving several basal ganglia nuclei, as well as the cortex, and that high-frequency stimulation of any of several points along the pathway can interfere with the oscillation.[371]

Preoperative evaluation should include ensuring that the coagulation system is intact and that the patient is not taking platelet-inhibiting agents (including herbal medications). There should be careful explanation of the procedure, its likely duration, and the necessary restraints on patient movement.

Several constraints will confront the anesthesiologist including:

1. *Airway access*. Commonly, the stereotactic frame, of which there are many variations, is placed using local anesthetic and the patient undergoes an imaging study

before being brought to the operating room. In some instances, the frame will prevent mask application and ventilation, laryngoscopy, and neck extension. If a general anesthetic is to be used, an awake intubation occasionally may be required. The frame is often anchored to the operating room table. If sedation is to be used, the anesthesiologist should have certain knowledge of how to remove the device rapidly in an urgent situation (including knowledge of the whereabouts of the requisite key or spanner device).

2. *The effect of anesthetics on microelectrode recordings and symptoms.* Localization of deep brain stimulation electrodes typically involves the combination of stereotaxis with fine tuning by identification of the electrophysiologic footprint specific to the targeted nucleus (e.g., the subthalamic nucleus, globus pallidus interna). The sedative agents used must not interfere with that signature. The nature and duration of the effects of anesthetics (which probably vary from nucleus to nucleus) have not been systematically defined. Some surgeons and electrophysiologists may request, on a just-in-case basis, that no sedative agent whatsoever be given. That is likely to be unnecessarily restrictive. Comprehensive reviews are available.[372-374] In short, benzodiazepines probably have the greatest potential to interfere and are best avoided. Propofol has been reported to cause severe dyskinesia in patients with movement disorders,[375] but has nonetheless been used quite frequently. At a minimum, a substantial interval between propofol administration and recording should be planned. Dexmedetomidine in low doses has been used quite widely without reports of interference with signals.[376] Remifentanil, in part because of its rapid clearance, is probably also a reasonable choice, although it too has been reported to suppress Parkinsonian tremor.[377] The cessation of the patient's symptoms upon stimulation, without the occurrence of unacceptable side effects, is also an important end point for determining the adequacy of deep brain stimulation position and stimulus parameters. The symptoms must not be suppressed by the sedative agents. This can occur with propofol.[378] Satisfactory electrophysiologic recordings and preservation of the tremor have been reported in Parkinsonian patients who received dexmedetomidine in a dose sufficient to maintain a lethargic response to normal speech.[352,376,379] An additional issue that arises in some patients with movement disorders is the problem of obtaining high-quality radiologic images in the presence of a persistent tremor. Sedation immediately preceding the stereotactic placement may be inevitable. Propofol has been used, but the window between propofol administration and subsequent recording should be as long as possible.
3. *Intracerebral hematoma and prevention of hypertension.* Intracerebral hematoma is a serious, potential intraoperative complication of stereotactic procedures. Prevention and prompt treatment of hypertension are among the anesthesiologist's important objectives. The concern is that, in the face of multiple needle passes through the brain, hypertension will precipitate development of an intracerebral hematoma. In the event of a substantial hematoma, an urgent craniotomy may be required, and the anesthesiologist should be prepared from the outset for this eventuality.

As noted in the section VAE, because of spontaneous ventilation, there is some hazard of VAE during deep brain stimulation placement.[95]

NEUROENDOSCOPIC PROCEDURES

Excision of some intraventricular lesions (e.g., colloid cysts, fenestration of the lamina terminalis or the floor of the third ventricle for treatment of hydrocephalus) can be accomplished endoscopically. Access is usually achieved through burr holes placed over the frontal or occipital horns of the lateral ventricle. The important anesthetic consideration relates to the irrigation fluid (which should be warmed) used to maintain clear visualization, in a manner analogous to orthopedic arthroscopy procedures. Obstruction to the effluent limb produces rapid increases in ICP that are commonly associated with sudden changes in vital signs. An increase in blood pressure and decrease in heart rate (a Cushing-type response) is classic, but the heart rate component is less reliable. Cardiovascular changes may also, but less predictably, represent mechanical irritation of intracranial (e.g., hypothalamic) structures. The surgeon should be notified immediately of any sudden hemodynamic changes. The decision of whether intraarterial monitoring is warranted should be made with the surgeon.

NEUROINTERVENTIONAL PROCEDURES

A wide variety of interventional procedures are performed for the evaluation and treatment of intracranial and extracranial disease. These include: stent-assisted revascularization for atherosclerotic disease; thrombectomy in the setting of acute thromboembolic disease; aneurysm, AVM, tumor, and arteriovenous fistula embolization; and treatment of cerebral vasospasm.[380]

Much of the management of neurointerventional anesthesia has been discussed previously in the section Recurrent Issues in Neuroanesthesia. Critical components of interventional neuroanesthesia include patient immobility, rapid anesthetic emergence to facilitate neurologic examination, strict hemodynamic manipulation to prevent hyperperfusion and hypoperfusion, and thoughtful $PaCO_2$ management. Additionally, the anesthesiologist may need to manage (and potentially reverse) anticoagulation. Inherent to neurointerventional procedures is a requisite knowledge of vascular anatomy and appreciation of the underlying pathology. Close communication with the interventionalist throughout the procedure is paramount. Cerebral vascular anatomy, including anatomic vascular distribution is reviewed in Fig. 57.21.

ANESTHETIC TECHNIQUE

GA is widely employed for a variety of reasons: (1) to ensure the immobility that is essential to the technical elements of the procedure; (2) to ensure patient comfort during particularly stimulating procedures; or (3) to control medical comorbidities or neurologic condition of the patient. Protection of the airway and control of ventilation ($PaCO_2$ manipulation, apnea) may also factor into a decision to employ GA. The potential disadvantages of GA include hemodynamic instability during intubation, extubation, or both;

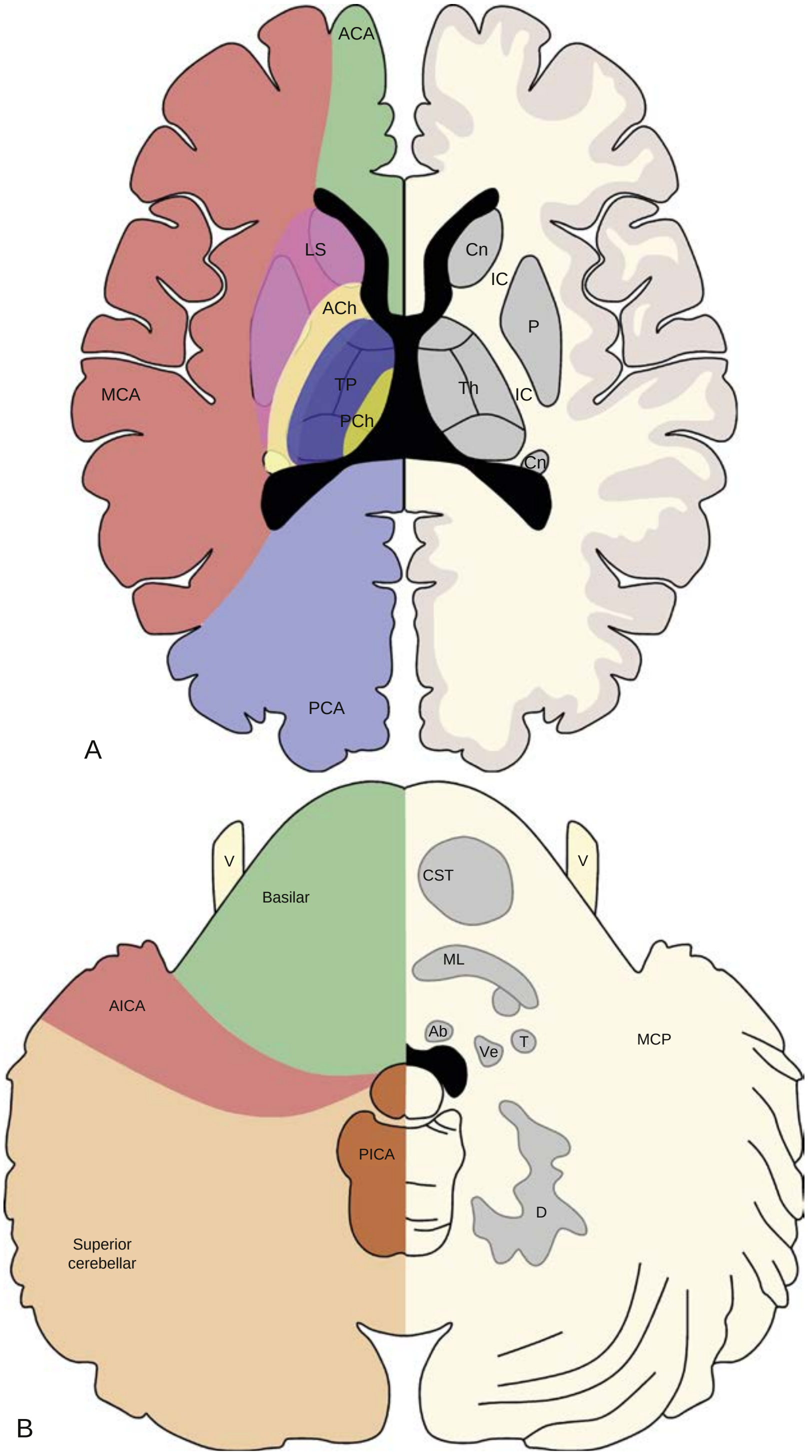

Fig. 57.21 Anatomic cerebral vascular distribution. *Ab*, Abducens nucleus; *ACA*, anterior cerebral artery; *ACh*, anterior choroidal artery; *AICA,* anterior inferior cerebellar artery; *CST*, corticospinal tract; *Cn*, caudate nucleus; *D*, dentate nucleus; *IC*, internal capsule; *LS*, lenticulostriate arteries; *MCA*, middle cerebral artery; *MCP*, middle cerebral peduncle; *ML*, medial lemniscus; *P*, putamen; *PCA*, posterior cerebral artery; *PCh*, posterior choroidal artery; *PICA,* posterior inferior cerebellar artery; *T*, trigeminal nucleus; *Th*, thalamus; *TP*, thalamic perforators; *V*, trigeminal nerve; *Ve*, vestibular nucleus.

anesthetic-induced hypotension causing cerebral hypoperfusion; inability to directly monitor the patient's neurologic status; complications related to coughing and straining during extubation; and delayed emergence or impaired postprocedure neurologic exam due to residual anesthetic drugs.

If GA is employed, there is little evidence to favor specific anesthetic agents over others provided basic neuroanesthetic goals are achieved (strict hemodynamic control, rapid emergence with minimal residual anesthetic effect on neurologic exam, and smooth emergence/extubation). Some advocate the avoidance of N_2O due to the potential of air bubble introduction into the arterial system during the procedure. Although N_2O could expand such bubbles and potentially increase ischemic risk, local experience of the authors suggests that N_2O is safe provided the interventional technique is meticulous.

MAC with intravenous sedative drugs has been advocated in the interventional radiology suite for various reasons (i.e., better maintenance of CPP, avoidance of hemodynamic lability at induction/emergence, preservation of neurologic exam, expedience). Although these reasons make intuitive sense, it remains unclear whether the anesthetic type truly provides a clear advantage in many of these areas.

ACUTE THROMBECTOMY

The frequency with which anesthesia personnel are enlisted to participate in the care of acute stroke patients having emergent thrombectomy is likely to increase because of the publication of recent studies demonstrating outcome improvement in select patients who undergo thrombectomy as long as 24 hours after the onset of stroke symptoms.[381,382] There has been some debate in recent years regarding the best anesthetic type (GA vs. MAC) for this procedure. Many retrospective studies found an association between GA and worse neurologic outcome following acute thrombectomy procedures.[383] Inherent in these studies was an obvious selection bias; airway control is generally sought for patients who have significant neurologic deficits and altered level of consciousness that precludes patient cooperation. Subsequent RCTs[384,385] and a recent meta-analysis[386] did not demonstrate an outcome benefit of MAC in this patient population. Although MAC has the potential to hasten vascular access time (imaging to groin puncture time),[383] recent studies have failed to demonstrate an advantage in time to revascularization.[383-385] Presumably this is because the small time delay attributed to endotracheal intubation was offset by reduced patient mobility and improved operative conditions. It should be noted that both MAC and GA can cause significant reduction in blood pressure and thereby increase risk of infarct to the ischemic penumbra; however, close attention to, and aggressive treatment of, hypotension by the anesthesiologist appears to negate the potential increased risk of GA-induced hypotension. In select patients (cooperative), MAC may allow for neurologic examination throughout the procedure, which may also serve to provide a therapeutic endpoint during thrombectomy procedures. At the present time, there is insufficient evidence to routinely recommend one anesthetic technique over another. Rather, the technique employed should be based upon a rapid clinical assessment of the patient, comfort level of the anesthesiologist with various techniques, and local practice. When GA is selected, attention must be given to avoid undue delay in endovascular treatment and to the maintenance of cerebral perfusion near awake levels. It is probably also reasonable to maintain normocapnia and to avoid profound hyperoxia.

Tumors and Arteriovenous Malformations

Hyperventilation may be appropriate in an attempt to divert flow away from normal brain and toward a lesion that is intended to receive the occlusive device or material. When the interventionalist is attempting to place glue in high-flow lesions (e.g., AVMs, fistulas), the anesthesiologist may be asked to reduce systemic blood pressure to prevent glue passage into the draining veins or systemic venous system. The choice of hypotensive agent depends on the anesthesiologist's experience and systemic cardiovascular considerations. Adenosine, which produces temporary flow cessation, is almost certainly the most effective means of accomplishing this objective.[387]

Intracranial Aneurysms

The International Subarachnoid Aneurysm Trial and subsequent meta-analysis have confirmed the broad applicability of endovascular treatment of aneurysms,[388,389] and the majority of aneurysms are currently managed by those approaches. Nonetheless, a substantial number of patients continue to undergo operative clipping,[390] primarily those with wide-necked aneurysms, diseased or occluded proximal vessels, and otherwise complex anatomy.

Many aneurysm-related procedures, in particular those involving the treatment of vasospasm by selective intraarterial administration of vasodilators (papaverine, calcium-channel blockers) or more commonly by balloon dilatation, can be accomplished without the involvement of an anesthesiologist. The duration of a procedure, individual patient factors, and sometimes the necessity for precise physiologic control may result in requests for MAC or GA. Absolute immobility is commonly needed by the interventionalist and is often the basis for a request for GA. In addition, anesthesiologists may become involved during the resuscitation stage in the event of vascular rupture or of the migration of an intravascular device to an incorrect location. In the event of rupture, the interventionist may request blood pressure reduction while the coil packing of the aneurysm is completed hastily. In addition, immediate reversal of heparinization is required. When detachable devices, such as coils and balloons (the latter now used infrequently), are misplaced and ischemia ensues, fluid loading and pressor administration may be requested to improve collateral CBF while the device is retrieved. A dedicated arterial line is usually warranted. This may or may not be available via a port in the interventionist's vascular access sheath. When these complications do occur, close communication with the interventionalist is essential to ensure appropriate response from the anesthesia team.

Stent-Assisted Revascularization or Stent-Assisted Aneurysm Coil Embolization

Endovascular stent placement typically requires preparation with dual antiplatelet therapy for 5 to 7 days. Aspirin and clopidogrel inhibition assays may be performed on the day of the procedure to confirm patient compliance and physiologic drug response.[391] Efficacious dual antiplatelet preparation to prevent early in-stent thrombosis may be particularly critical with the use of flow diverting stents (e.g., pipeline embolization device) that possess a larger total metal surface area. Carotid artery stent (CAS) placement may be performed as an alternative to CEA, particularly if the vascular anatomy is unfavorable for CEA or significant concern for coronary artery disease exists. Hypotension and/or bradycardia should be anticipated at the time of stent deployment[392] and temporary vasopressor support and/or pharmacologic treatment of bradycardia may be required.

CEREBROSPINAL FLUID SHUNTING PROCEDURES

CSF shunts are inserted for the relief of a variety of hydrocephalic states and pseudotumor cerebri. Hydrocephalus can be communicating or noncommunicating. In a noncommunicating hydrocephalus, CSF egress from the ventricular system is obstructed. This can occur as a result of blood or infection in the ventricular system or tumors in or adjacent to the ventricular system. In communicating hydrocephalus, the CSF escapes from the ventricular system but is not absorbed by the arachnoid villi. This occurs most commonly secondary to infection or blood in the CSF space. Some degree of communicating hydrocephalus is particularly common after SAH.

Placement of a ventriculoperitoneal shunt is the most common procedure. Usually a catheter is inserted via a burr hole into the frontal horn of the lateral ventricle on the nondominant (usually the right) side. A reservoir is placed subcutaneously adjacent to the burr hole and the drainage limb passes via a subcutaneous tunnel to a point near the epigastrium, where it is inserted into the peritoneal space via a very small laparotomy. A moderate degree of muscle relaxation may be helpful. A distended stomach can result in an inadvertent gastrostomy. Sometimes, most commonly in pediatric patients, there may be an obstruction at more than one level in the ventricular system and a so-called double-barreled shunt becomes appropriate. In this instance, there are two proximal ends, usually one in a lateral ventricle and one in the fourth ventricle. This latter procedure is usually performed in the prone position, whereas the majority of ventriculoperitoneal shunts are done supine.

Occasionally, when there is a communicating hydrocephalus, a lumboperitoneal shunt is inserted. The patient is placed in a lateral position and a catheter is put in the lumbar CSF space via a Tuohy-type needle. The catheter is tunneled subcutaneously around to the anterior abdominal wall and inserted into the peritoneal space via a small laparotomy.

Anesthetic Management

Invasive monitoring is generally not required. The anesthetic technique should be chosen to avoid further increases in ICP. Moderate hyperventilation ($PaCO_2$ 25-30 mm Hg) is customary. Because these procedures are not performed in the context of acute injury states, there is less concern about adverse effects of hypocapnia. The target $PaCO_2$ should be agreed upon at the outset with the surgeon. The procedure is usually performed in the supine position. Blood pressure may decrease abruptly when the ventricle is first cannulated (as brainstem pressure is relieved). Infrequently, brief pressor support is required. Burrowing the subcutaneous tunnel can produce a sudden painful stimulus. There is only minor postoperative discomfort. Unlike the majority of neurosurgical patients, shunt patients are often nursed flat after their procedures in an attempt to prevent an excessively rapid collapse of the ventricular system. Empirically, there is a small incidence of subdural hematoma after shunting, and the tearing of bridging veins at the time of rapid brain shrinkage is a suspected cause.

Pediatric Ventriculoperitoneal Shunts

Shunts are probably more commonly performed in children than in adults. Common indications are hydrocephalus occurring in association with meningomyelocele, neonatal intraventricular hemorrhage, and posterior fossa tumors. Although one can never be casual about the management of these patients, open fontanelles seem to provide some margin for error in younger patients and, in addition, palpation of the fontanelles provides on-line trend monitoring of ICP. Despite its theoretic considerations, inhaled inductions using volatile anesthetics are empirically well tolerated, even in children with closed fontanelles. We avoid the inhaled induction technique in a child who was already stuporous. When an intravenous line is available, a propofol-relaxant induction sequence is preferable. For children in whom cannulation of a peripheral vein cannot be accomplished readily, an inhaled induction with sevoflurane is a common approach, with initiation of controlled ventilation, by bag and mask, as rapidly as possible. After establishing controlled ventilation, an ideal course at this point is to establish an intravenous line and administer a muscle relaxant and perhaps an induction agent, and then intubate the trachea in these optimal circumstances. For children older than 6 months of age who are not stuporous at the outset, we commonly titrate in fentanyl in the belief that this procedure is not entirely pain-free postoperatively, and that a smoother emergence can be accomplished with a narcotic background.

PEDIATRIC NEUROSURGERY

Table 57.6 identifies common pediatric procedures and their anesthetic considerations. The most frequent procedures are probably the placement and revision of CSF shunts (discussed in the preceding section). The majority of pediatric tumors occur in the posterior fossa. Most are near the midline and many are associated with hydrocephalus. For pediatric posterior fossa procedures, VAE risk, monitoring, and treatment are similar for adults and children and have been previously discussed. A Doppler probe and right heart catheters are frequently placed when procedures are done in the sitting position. Craniosynostosis procedures have the potential for substantial blood loss that is roughly proportional to the number of sutures involved. There is a significant VAE risk that justifies the use of a precordial Doppler.[93] Children with neuraxial tumors can present for emergent palliative radiotherapy and may have acutely increased ICP or impending herniation. Intractable pain combined with analgesic tolerance, steroid use causing centripetal obesity, and the side effects of other chemotherapeutic agents may be complicating factors.

SPINAL SURGERY

Table 57.7 summarizes the many issues that may arise in the context of spinal cord or spinal column procedures undertaken by neurosurgeons.

Surgery on the spinal column is reviewed in detail in Chapter 66. The relevant electrophysiologic monitoring techniques are described in Chapter 39. Prone positioning has previously been discussed.

TABLE 57.6 Pediatric Neurosurgical Disorders and Their Anesthetic Considerations

Age Group	Lesion	Pathogenesis	Anesthetic Considerations
Neonates	Intraventricular hemorrhage	Subependymal vascular rupture	Associated problems of prematurity
	Depressed skull fracture	Forceps injury	Associated cerebral edema
	Meningocele	Out-pouching of meninges through skull defect	Large size creates airway management difficulty
			Prone or lateral position Repair may increase ICP Variable blood loss
	Encephalocele	Out-pouching of meninges and brain through skull	As above
	Meningomyelocele	Protrusion of meninges and nerve roots through spina bifida	Prone or lateral position Respiratory restriction after covering large defects
Infants	Hydrocephalus	Varied	Increased ICP
	Arnold-Chiari malformation	Posterior fossa contents compressed in foramen magnum	Brainstem compression with neck flexion ± Hydrocephalus/Increased ICP; ± Meningomyelocele; Postoperative respiratory depression
	Craniosynostosis	Premature fusion of cranial sutures	Open or endoscopic procedure Substantial blood loss Air embolism Supine or prone
	Craniofacial dysostosis	Developmental abnormality	Lengthy procedures Substantial blood loss Brain retraction Air embolism Endotracheal tube damage
	Vascular malformations	Varied	Congestive heart failure Large blood loss Induced hypotension
	Subdural hematoma	Trauma	Associated injuries
Older pediatrics	Posterior fossa tumors	Ependymoma	Hydrocephalus
		Astrocytoma	Increased ICP
		Medulloblastoma	Prone or sitting position
		Teratoma	Air embolism
		Brainstem glioma	Brainstem compression Postoperative cranial nerve dysfunction or brainstem swelling or compression

ICP, Intracranial pressure.

The physiology of the spinal cord is, in general, similar to that of the brain: CO_2 responsiveness, BBB, autoregulation, high metabolic rate and blood flow (though somewhat less than the brain), and substantial ischemic vulnerability of gray matter. However, measures to reduce spinal cord swelling, analogous to ICP reduction maneuvers, are rarely used. The anesthesiologist should be attentive to situations in which there is significant compression of the spinal cord. This arises most often in the setting of cervical spinal stenosis and should be assumed to be present with fracture dislocation of the spinal column. For these patients, we place arterial catheters and support blood pressure carefully. We believe that in these settings, and in patients with recent spinal cord injury (<7 days), blood pressure should be maintained at a MAP of 85 to 90 mm Hg or waking baseline level, whichever is higher. Blood pressure support is less important when the issue is nerve root rather than spinal cord compression. The presence of spinal stenosis and chronic cord compression is frequently, but not invariably, associated with lower extremity hyperreflexia and ankle clonus. Awake intubation may be warranted when there is instability of the cervical spinal column and in some instances of severe cervical spinal stenosis in which it is perceived that minor degrees of flexion or extension, or both, might critically aggravate spinal cord compression. Preintubation discussion and agreement with the surgeon is appropriate.

TABLE 57.7 Anesthetic Considerations and Position Requirements Associated With Various Spinal Surgical Procedures

Spinal Segment and Surgical Condition	Problems and Considerations	Positions Used and Comments
Cervical region: Spinal stenosis, trauma, rheumatoid arthritis, degenerative disk disease	Maintain neutral neck position to avoid cord compression	Supine/anterior approach for most discectomies Posterior approach (prone or sitting) for laminectomy and pedicle screws
	Maintain perfusion pressure near waking normal levels	If existing cord compression, recent cord injury, or if cord retraction is required
	Hypotension (spinal shock)	Occurs with complete cervical cord injury
	Postoperative respiratory insufficiency	Occurs with cervical cord injury
	Air embolism	With sitting laminectomies
Anterior cervical discectomy	Retractor compression of airway Postoperative swelling/airway compression Postoperative cranial nerve dysfunction	Supine Traction may be required for graft insertion endotracheal tube cuff deflation/reinflation after retractor placement
Cervical instability	Awake intubation Awake positioning Manual in-line stabilization for intubation (if awake intubation is not feasible)	Prone or supine
Thoracolumbar region: degenerative disease, spinal stenosis, trauma	Major position change Awake intubation and position	Prone, lateral, or knee-chest If unstable, post trauma and/or major position change required
	Blood loss	Especially with redos, instrumentations, and spinal stenosis; risk of occult aorto- iliac or major venous injury
	Air embolism Postoperative vision loss	Infrequent Etiology unclear; associated with long prone procedures, low hematocrit, large estimated blood loss, and hypotension; patient variables may contribute (see Chapter 34)
Vertebral metastasis	Large blood loss	Prone or anterolateral/retroperitoneal Lung separation for lesions above L1
Spinal cord tumors	Maintain perfusion pressure during retraction	Prone
Procedures with major neurologic risk	Wake-up test (now rare) Somatosensory evoked responses Motor evoked responses Pedicle screw electromyogram	Rehearse with patient Anesthetic agent restrictions Anesthetic/relaxant restrictions Relaxant restriction

58 Anesthesia for Bariatric Surgery

GAURAV MALHOTRA and DAVID M. ECKMANN

KEY POINTS

- In the United States more than two out of three people are overweight or obese. Worldwide, more people are obese than are malnourished. Obesity is becoming the largest single preventable cause of death and represents major morbidity and mortality.
- Metabolic syndrome includes abdominal obesity, decreased high-density lipoprotein, insulin resistance, glucose intolerance, and hypertension, and is present in approximately 34% of the adult population in the United States alone.
- The single greatest risk factor for sleep apnea is obesity, with the majority of obese patients having increased oral and pharyngeal tissue. This makes ventilation, intubation, and extubation more challenging.
- Choices for medical management of obesity are limited and efficacious achievement with just medical management is uncommon. Changes in behaviors are important for success.
- Surgery for obesity is recommended at a body mass index (BMI) of 40 kg/m^2 or BMI over 30 kg/m^2 with comorbidities expected to respond to weight loss, secondary to surgical therapy, like hypertension, diabetes, and hypercholesterolemia. In clinical trials, long-term survival is better in the surgically treated group over the medically managed.
- Preoperative evaluation should focus on cardiopulmonary issues and securing an airway, along with other concerns such as diabetes, hypertension, and obstructive sleep apnea.
- Anesthetic drugs should be tailored based on lipid solubility and awareness of lingering respiratory depression effects.
- Patient preparation and positioning are keys to successful airway management. Preoperative pressure support ventilation should be used adjunctively if possible.
- Intraoperative ventilation is assisted by complete paralysis, moderate positive end-expiratory pressure, tidal volumes based on ideal body weight, and recruitment maneuvers as needed.
- Common serious postoperative complications are deep vein thrombosis and staple line issues.
- Obese patients presenting for nonweight-loss surgery benefit from anesthetic approaches similar to that used for bariatric surgery.

Obesity as a Disease

Obesity is firmly established as one of the great epidemics of the 21st century.[1] Worldwide, obesity was considered a rarity until the middle of the previous century,[2] but now there are 1.9 billion overweight adults and over 650 million obese people globally including a significant proportion of the adult population in the United States.[3-5] Obesity is a problem that is affecting the younger population as well since over 340 million children and adolescents aged 5 to 19 were overweight or obese in 2016.[6] Current estimates are that more than 2 out of 3 of the U.S. adult population are overweight or obese. Of these one in three adults has obesity and 1 in 13 has extreme obesity with a body mass index (BMI) greater than 40.[7] Among children and adolescents ages 2 to 19, about 1 in 6 are obese, and about 1 in 17 are considered to have extreme obesity.[8] Obesity and its associated health concerns are now major causes of morbidity and mortality resulting in an enormous impact on healthcare spending. Over 300,000 deaths per annum in the United States and about $270 billion[6] in annual healthcare spending are attributable to obesity, placing it second only to smoking as a preventable cause of death.[9]

Obesity can be defined as a disease since it is a physiologic dysfunction of the human organism with environmental, genetic, and endocrinologic etiologies.[9] Obesity most frequently develops when food caloric intake exceeds energy expenditure over a sustained period of time. Factors influencing obesity involve either energy intake or energy expenditure, and are influenced by genetic, behavioral, cultural, and socioeconomic factors.[10] For example, there are syndromes that are associated with obesity, including leptin deficiency, Prader-Willi syndrome, and Lawrence-Moon-Biedl syndrome.[4] Metabolic factors can influence energy regulation, including hormones, peptides, nutrients, uncoupling proteins, and neural regulatory substances emanating from gut, liver, brain, and fat cells, but most of these are not well understood.

The BMI is the most widely applied classification tool used to assess individual weight status.[11] The BMI is specifically defined as the patient's weight, measured in kilograms, divided by the square of the patient's height, measured

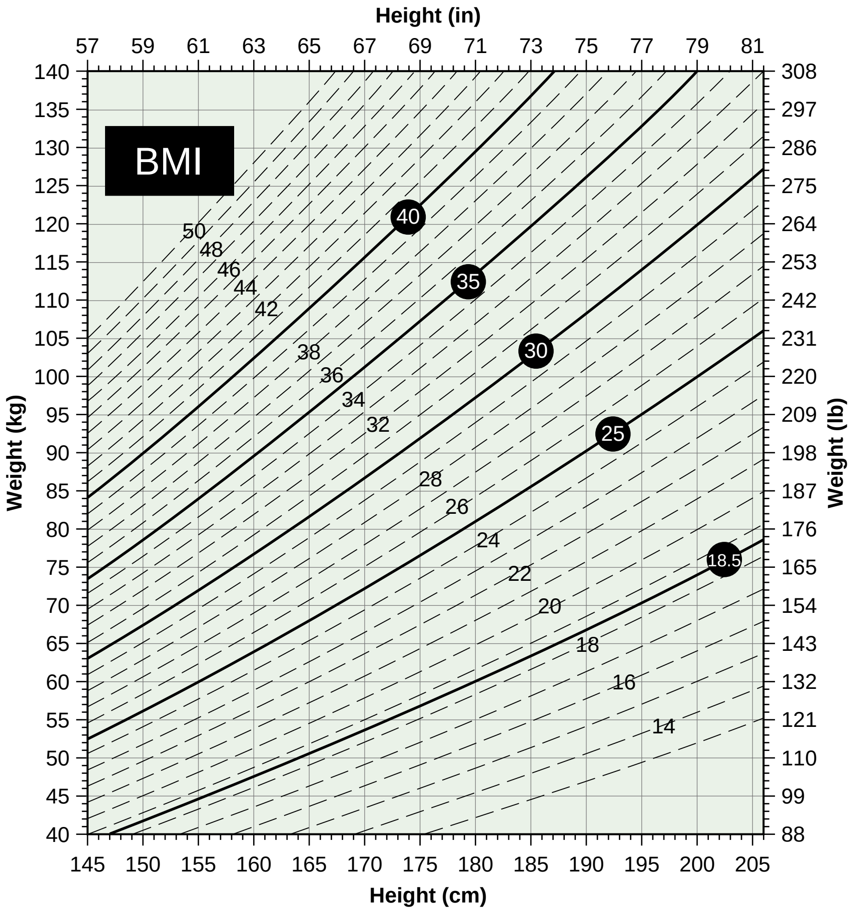

Fig. 58.1 A family of iso-body mass index *(BMI)* curves for BMI ranging from 13 to 50 and mapped on axes for height (in both centimeters and inches) and weight (in both kilograms and pounds).

in meters, yielding a measurement bearing units of kilograms per square meter (kg/m^2). Fig. 58.1 shows a family of iso-BMI curves for BMI ranging from 13 to 50 kg/m^2 and mapped on axes for height (in both inches and centimeters) and weight (in both pounds and kilograms). Most electronic medical record systems are programmed to indicate patient BMI when height and weight inputs are provided. The National Institutes of Health maintains an online BMI calculator and also provides links for downloadable smartphone BMI applications at https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmicalc.htm. Using this system, patients are classified according to BMI and the associated risk of developing health problems is shown in Table 58.1. Patients are considered to be overweight if they have a BMI between 25 and 29.9 kg/m^2, and they are classified as obese with a BMI between 30 and 49.9 kg/m^2. The obese classification is further subdivided into Class 1 (BMI range 30-34.9 kg/m^2), Class 2 (35-39.9 kg/m^2) and Class 3 (40-49.9 kg/m^2). Patients with a BMI of 50 kg/m^2 or greater are classified as superobese. As BMI increases beyond normal weight, the risk of developing serious health problems rises greatly and can be correlated with the individual's waist circumference (Table 58.2). Malnourishment and malnutrition are commonly offered as explanations for the fact that underweight patients are also at increased risk for developing illnesses.

TABLE 58.1 Levels of Risk Associated With Increasing Body Mass Index

Classification	BMI (kg/m^2)	Risk of Developing Health Problems
Underweight	<18.5	Increased
Normal weight	18.5-24.9	Least
Overweight	25.0-29.9	Increased
Obese		
Class 1	30.0-34.9	High
Class 2	35.0-39.9	Very high
Class 3	40.0-49.9	Extremely high
Superobese	≥50	Exceedingly high

BMI, Body mass index.

There are specific diseases commonly associated with obesity, and obesity is often accompanied by multiple, and not single, comorbid states.[7] These frequently include insulin resistance, type 2 diabetes mellitus, obstructive sleep apnea (OSA), asthma, chronic obstructive pulmonary disease, hypoventilation, cardiovascular disease, hypertension, certain malignancies, and osteoarthritis.[1,12-22] Virtually every

TABLE 58.2 Waist Circumference and Risk

Waist	BMI (KG/M^2)		
Circumference	**Normal Weight**	**Overweight**	**Obese Class 1**
<102 cm (♂) <88 cm (♀)	Least risk	Increased risk	High risk
≥102 cm (♂) ≥88 cm (♀)	High risk	Very high risk	Increased risk

TABLE 58.3 Health Risks Associated With Increasing Body Mass Index

Metabolic syndrome	30% of middle-aged people in developed countries have features of metabolic syndrome
Type 2 diabetes	90% of type 2 diabetics have a BMI of >23 kg/m^2
HTN	5× risk in obesity 66% of HTN is linked to excess weight 85% of HTN is associated with a BMI >25 kg/m^2
CAD	3.6× risk of CAD for each unit change in BMI
CAD and stroke	Dyslipidemia progressively develops as BMI increases from 21 kg/m^2 with rise in small particle low-density lipoprotein 70% of obese women with HTN have left ventricular hypertrophy Obesity is a contributing factor to cardiac failure in >10% of patients Overweight/obesity plus hypertension is associated with increased risk of ischemic stroke
Respiratory effects (e.g., obstructive sleep apnea)	Neck circumference of >43 cm in men and >40.5 cm in women is associated with obstructive sleep apnea, daytime somnolence, and development of pulmonary hypertension
Cancers	20% of all cancer deaths among nonsmokers are related to obesity (30% of endometrial cancers)
Reproductive function	6% of primary infertility in women is attributable to obesity Impotency and infertility are frequently associated with obesity in men
OA	Frequent association in the elderly with increasing body weight—risk of disability attributable to OA equal to heart disease and greater to any other medical disorder of the elderly
Liver and gall bladder disease	Overweight and obesity associated with nonalcoholic fatty liver disease and NASH. 40% of NASH patients are obese; 20% have dyslipidemia 3× risk of gall bladder disease in women with a BMI of >32 kg/m^2 7× risk if BMI of >45 kg/m^2

BMI, Body mass index; *CAD,* coronary artery disease; *HTN,* hypertension; *NASH,* nonalcoholic steatohepatitis; *OA,* osteoarthritis;

organ system can be included in the extended list of health risks associated with having an abnormally elevated BMI. A listing of the most common specific disease states along with their obesity-associated risk is detailed in Table 58.3. As a result, obesity is also associated with early death.[11,23]

BOX 58.1 Features Associated With Metabolic Syndrome

Abdominal obesity
Atherogenic dyslipidemia (↑ TGs, ↓ HDL-C, ↑ ApoB, ↑ small LDL particles)
Elevated blood pressure
Insulin resistance ± glucose intolerance
Proinflammatory state (↑ hsCRP)
Prothrombotic state (↑ PAI-1, ↓ FIB)
Other (endothelial dysfunction, microalbuminuria, polycystic ovary syndrome, hypoandrogenism, non-alcoholic fatty liver disease, hyperuricemia)

ApoB, Apolipoprotein-B; *FIB*, fibrinogen; *HDL-C*, high-density lipoprotein cholesterol; *hsCRP*, high-sensitivity C-reactive protein; *LDL*, low-density lipoprotein; *PAI-1*, plasminogen activator inhibitor; *TG's*, triglycerides.

Of all the health risks included in Table 58.3, metabolic syndrome and OSA merit additional attention as they pose special concerns for the anesthetic care of obese patients.

METABOLIC SYNDROME

The clustering of a group of defined metabolic and physical abnormalities is now referred to as the metabolic syndrome.[24] Patients with metabolic syndrome commonly have abdominal obesity, reduced levels of high-density lipoprotein (HDL), hyperinsulinemia, glucose intolerance, hypertension, and other characteristic features[15] as listed in Box 58.1. Specific criteria for diagnosing metabolic syndrome are included in Table 58.4. The diagnosis requires that at least three of the following be present: abdominal obesity, elevated fasting glucose, hypertension, low HDLs, and hypertriglyceridemia.[25] Weight gain with visceral obesity is a major predictor of the metabolic syndrome. The clinical approach uses waist circumference, rather than BMI, to define the adipose mass component contributing to the metabolic syndrome since BMI has been shown to be a relatively insensitive indicator of the risk for obesity-associated metabolic and cardiovascular diseases. Waist circumference, but not BMI, reflects abdominal subcutaneous adipose tissue as well as abdominal visceral adipose tissue and is therefore a better index of central, or truncal, fat mass.

In the United States, approximately 34% of the adult population have metabolic syndrome.[26] Of these, more than 83% meet the criterion of abdominal obesity. The incidence of metabolic syndrome increases with age, with more than 40% of the U.S. population affected by the age of 60 years.[24] Men are affected more commonly than women, and Hispanics and South Asians appear to be particularly susceptible. Its frequency is lower in African American men than in Caucasians. Metabolic syndrome may result from use of some commonly prescribed drugs, including corticosteroid, antidepressant, and antipsychotic agents. Protease inhibitors used to treat human immunodeficiency virus (HIV) infection can induce metabolic syndrome secondary to insulin resistance.

Patients with metabolic syndrome have an increased risk for cardiovascular disease events and are at increased risk for all-cause mortality. Metabolic syndrome increases

TABLE 58.4 Clinical Criteria for Diagnosing Metabolic Syndrome

Central obesity	Waist circumference >102 cm in men Waist circumference >88 cm in women
Plus any two of the following:	
Criteria	**Defining Value**
Triglycerides	150 mg/dL (1.7 mmol/L), or Specific treatment for this lipid abnormality
High-density lipoprotein cholesterol	<40 mg/dL (1.03 mmol/L) in men, or <50 mg/dL (1.29 mmol/L) in women, or Specific treatment for this lipid abnormality
Blood pressure	Systolic blood pressure >130 mm Hg, or Diastolic blood pressure >85 mm Hg, or Treatment of previously diagnosed hypertension
Fasting glucose	110 mg/dL (5.6 mmol/L), or Previously diagnosed type 2 diabetes

the risk of type 2 diabetes, which itself is an important risk factor for atherosclerotic disease and may be considered as a coronary heart disease equivalent.[17,24] Metabolic syndrome is also associated with a variety of other conditions, such as polycystic ovary syndrome, nonalcoholic fatty liver disease, gallstones, sleep disturbances, sexual impotence, and numerous forms of cancer including breast, endometrial, pancreatic, colon, and liver cancer, as detailed in Table 58.3.[27] In multiple trials involving nearly 1900 patients, morbidly obese individuals had much greater weight loss following bariatric surgery than after nonsurgical therapy, with amelioration of most of the diseases associated with morbid obesity in a year's time.[28] Metabolic syndrome is resolved by bariatric surgery in over 95% of patients who achieve the expected weight loss,[29] making it clear that bariatric surgery is a metabolic intervention and not simply a weight management procedure.[30]

Inflammatory processes appear to play an important role in the metabolic syndrome.[20] Adipose tissue has two major functions: storage and release of energy-rich fatty acids and secretion of proteins required for endocrine and autocrine regulation of energy metabolism. Adipocytes exert their metabolic effects by release of free fatty acids, whose release is enhanced by the presence of catecholamines, release of glucocorticoids, increased beta-receptor agonist activity, and reduction of lipid storage mediated by insulin. Visceral adipose tissue has been identified as an important source of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6), as well as antiinflammatory cytokines such as adiponectin. Increased levels of proinflammatory cytokines likely contribute to the etiology of insulin resistance primarily by obstructing insulin signaling and contributing to downregulation of peroxisomal proliferator-activated receptor-γ, which are fundamentally important regulators of adipocyte differentiation and control. Additionally, insulin resistance may promote inflammation through diminution of insulin's antiinflammatory effects. Lastly, oxidative stress is increased with obesity, primarily as a result of excessive intake of macronutrients and a concomitant increase in metabolic rate. These factors may also contribute to the inflammatory response noted with obesity.[20]

Native immune responses act aberrantly in obese individuals. Natural killer (NK) cell cytotoxic activity is depressed with obesity, as are plasma levels of cytokines such as IL-12, IL-18, and interferon-γ known to regulate NK cell function.[31] Other cytokines (primarily IL-6 and TNF-α) and adipokines (leptin, adiponectin, adipose-derived resistin) are two additional major groups of inflammatory proteins produced and released by adipose and adipose-associated tissue.[20] Both serum and adipose tissue obtained from obese subjects consistently have elevated levels of IL-6 and TNF-α, and circulating levels of IL-6 are consistently increased in individuals having either type 2 diabetes or impaired glucose tolerance. Proteins such as leptin and adiponectin, which are produced primarily by adipocytes, are classified as adipokines. Although leptin is primarily involved in appetite control, its immunologic effects include protection of T lymphocytes from apoptosis and regulation of T-cell activation and proliferation. Reduced leptin levels may increase appetite and slow metabolism, but may also increase susceptibility to the toxicity of proinflammatory stimuli, such as endotoxin and TNF-α. Elevated leptin levels are proinflammatory, and this likely plays an important role in the progression of heart disease and diabetes, especially in obese patients. Serum levels of adiponectin correlate with insulin sensitivity and do not rise in obesity. Significantly reduced adiponectin levels are found in patients having type 2 diabetes. Adiponectin reduces both TNF-α production and activity. It also inhibits IL-6 production. Resistin, an adipokine that induces insulin resistance, is induced by endotoxin and cytokines. Resistin acts at the cellular level to upregulate production of proinflammatory cytokines, most likely through the nuclear factor κB (NFκB) pathway. Resistin appears to present a molecular link among metabolic signaling, inflammatory processes, and the development of cardiovascular disease. Resistin levels have been associated with inflammatory markers apparently independent of BMI in humans.[20]

An understanding of the role of NFκB in insulin resistance is required to fully appreciate the links between obesity and inflammation. Both free fatty acids and TNF-α act via intracellular inflammatory cascade pathways to arrest insulin signaling. This process is mediated by activation of transcription factors present within the cell cytoplasm. Following their translocation to the nucleus, they eventually bind to transcription factors regulating the inflammatory process. The cytoplasm also contains NFκB, another transcription factor whose activation is implicated in a number of diseases, including diabetes. NFκB is also induced by hypoxia, and it increases production of proinflammatory cytokines TNF-α and IL-6, both of which are frequently increased in patients with OSA syndrome.[20] Therefore inflammation provides the common linkage underlying the association between obesity, metabolic syndrome, and OSA.[32]

OBSTRUCTIVE SLEEP APNEA—HYPOPNEA SYNDROME

OSA is a condition characterized by recurrent episodes of partial or complete upper airway collapse occurring during sleep.[33] An obstructive apneic event is defined universally as the complete cessation of airflow during breathing lasting 10 seconds or longer despite maintenance of neuromuscular ventilatory effort. The definition of an obstructive hypopneic event however may vary depending on the criteria being used for scoring. The Centers for Medicare and Medicaid Services (CMS) defines a hypopneic event as the partial reduction of airflow of 30% or more lasting at least 10 seconds, accompanied by a decrease of at least 4% in the oxygen saturation (SpO_2) as opposed to the American Academy of Sleep Medicine (AASM), which accepts a 3% drop in SpO_2 or a terminal cortical arousal. Additionally, the AASM recommends scoring a third type of respiratory event in which flow limitation is detected and is associated with a cortical arousal. These events are designated respiratory effort related arousals (RERAs).

The diagnosis of OSA can only be made in patients who undergo polysomnography, or a home sleep study.[33] Results of polysomnography are reported as the apnea-hypopnea index (AHI), which is derived from the total number of apneas and hypopneas divided by the total sleep time or the respiratory disturbance index (RDI) which includes RERA. A normal lower limit for AHI has not yet been defined in an epidemiologic study of healthy subjects. Most sleep centers commonly use an AHI between 5 and 10 events per hour as a normal limit. The severity of obstructive sleep apnea/hypopnea syndrome (OSAHS) is arbitrarily defined, but recommendations for disease classification are as follows[33]:

Mild Disease: AHI of 5 to 15 events per hour
Moderate Disease: AHI of 15 to 30 events per hour
Severe Disease: AHI of greater than 30 events per hour

Due to the risks of developing systemic and pulmonary hypertension, left ventricular hypertrophy, cardiac arrhythmias, cognitive impairment, persistent daytime somnolence, and other factors, treatment is recommended for patients with either moderate or severe disease. Treatment partly depends on the severity of the sleep-disordered breathing, but the consensus view is that patients with moderate or severe disease should be treated with continuous positive airway pressure (CPAP) during sleep. Other conservative treatment measures may include weight loss, avoidance of alcohol prior to bedtime, and sleeping on one's side.

Numerous studies have confirmed that obesity is the greatest risk factor for OSAHS, with about 70% of patients (up to 80% of males and up to 50% of females) with OSAHS being obese. Severe sleep apnea disease is more common in men until women reach the age of menopause, and a strong negative correlation between the AHI and minimum SpO_2 has been observed. Importantly, the diagnosis of OSAHS may be missed until the patient presents for surgery. In one study of 170 patients presenting for surgery, only 15% had already been diagnosed with sleep apnea, but on preoperative testing, 76% were found to have OSAHS.[34] A STOP-Bang questionnaire (Box 58.2) can be used to screen patients for OSA, with a score of 5 to 8 identifying patients at risk for moderate to severe disease.[35] We believe it is important for obese patients presenting for bariatric surgery to undergo preoperative polysomnography testing for OSAHS. Preoperative diagnosis and appropriate interventional management can have the following benefits: less postoperative sleep deprivation, improved response to analgesic and anesthetic drugs, and normalization of cardiovascular disturbances.[36]

BOX 58.2 **STOP-Bang Questionnaire**

1. Snoring: Do you snore loudly (loud enough to be heard through closed doors)?
2. Tired: Do you often feel tired, fatigued, or sleepy during daytime?
3. Observed: Has anyone observed you stop breathing during your sleep?
4. Blood pressure: Do you have or are you being treated for high blood pressure?
5. BMI: BMI more than 35 kg/m^2?
6. Age: Age over 50 years old?
7. Neck circumference: Neck circumference >40 cm?
8. Gender: Male?

High risk of OSA: Yes to ≥3 questions.
Low risk of OSA: Yes to <3 questions.
BMI, Body mass index; *OSA*, obstructive sleep apnea.

Anatomically, obese patients with OSAHS typically have increased amounts of adipose tissue deposited into oral and pharyngeal tissues including the uvula, tonsils, tonsillar pillars, tongue, aryepiglottic folds, and lateral pharyngeal walls. An inverse relationship exists between the degree of obesity and pharyngeal area. Deposition of fat in the lateral walls decreases the size of the airway and changes the shape of the oropharynx into an ellipse with a short transverse and long anteroposterior axis.[37-39] This configuration can contribute to both the development and severity of airway obstruction and can also increase the expectation that it will be more difficult to maintain airway patency during mask ventilation and to perform direct laryngoscopy for endotracheal intubation with general anesthesia.[40-41] Neuromuscular blockade should be fully reversed prior to extubation, and low tidal volumes or lung protective ventilation should be employed.

Additionally, airway obstruction following extubation is likely to be complicated by the use of opiate and sedative drugs needed for postoperative pain management because these drugs tend to decrease pharyngeal dilator tone and increase the likelihood of upper airway collapse.[40]

OSA also plays an important role in inflammation and the metabolic syndrome.[20,32] The hypopneic and apneic events that occur in OSAHS are part of the cycle of events that involves both arousal from sleep and oxyhemoglobin desaturation. Sympathetic nervous system activation results as patients with untreated OSA undergo cyclic episodes of hypoxia and reoxygenation. This process leads to elevation of proinflammatory cytokines and may also induce oxidative stress of vascular endothelium, thus inducing an even more heightened state of systemic inflammation in obese patients with OSA.[32] Levels of many different inflammatory mediators, including IL-6, high-sensitivity C-reactive protein (hs-CRP), leptin, TNF-α, IL-1, reactive oxygen species, and adhesion molecules, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), are increased in patients with OSAHS.[20] Thus obesity, the metabolic syndrome, and

OSAHS are interrelated diseases that significantly alter a patient's inflammatory disease profile and increase multiple health risks, particularly those of cardiovascular and airway origin. Importantly, surgical intervention to cause weight loss has been shown not only to improve obesity-related respiratory disease,[14] but it also can lead to significant and sustained increases in plasma adiponectin levels while decreasing both IL-6 and hs-CRP levels[42] as well as improve NK cell function and increase IL-12, IL-18, and interleukin-γ plasma levels.[31]

Nonsurgical Management of Obesity

The primary goals of nonsurgical management of obesity involve weight loss, the treatment of abnormalities associated with metabolic syndrome, and prevention of type 2 diabetes and cardiovascular disease-related events. Treatment of metabolic syndrome needs to follow an aggressive, multifaceted approach to address multiple underlying metabolic abnormalities and coexistent risk factors simultaneously.[24] An appropriate initial treatment of obesity and metabolic syndrome is therapeutic lifestyle change. This includes dietary modification, weight loss, physical activity, and discontinuation of smoking. The treatment aim is improvement in health, and is the primary reason for advocating weight loss. Modification of energy homeostasis is not easily achieved because a strong brain-gastrointestinal axis drives both food intake and satiety. This axis has hormonal components involving endogenous production of ghrelin, an orexigenic peptide that is produced by the foregut of the stomach and that stimulates appetite.[43] Therefore it is important to monitor the effects of treatment on risk factors and comorbidities at the systems, organ, cell, and molecular levels. Treatment success should be reflected in the decreasing need to treat other coexisting diseases.

The goal for weight loss in therapeutic lifestyle change is not the achievement of normal or ideal body weight (IBW). Even a modest weight loss, in the range of 5% to 10% from the presentation weight, can result in significant initial improvement in the comorbidities of diabetes, dyslipidemia, and hypertension by lowering total cholesterol and triglyceride levels, raising HDL-cholesterol, lowering arterial blood pressure, and lowering blood glucose values while reducing insulin resistance.[24,44] Obesity guidelines stress the need for weight reduction using behavioral change to reduce caloric intake and increase physical activity. A decrease in caloric intake is the most important component in achieving weight loss and increased physical activity is critical in maintaining the lost weight.[45] Reduced-energy diets are more effective and healthier for achieving long-term weight loss. Long-term maintenance of any weight loss achieved is best accomplished with the inclusion of regular exercise as a staple of the weight-reduction regimen. Regular physical exercise improves several risk factors associated with obesity and metabolic syndrome.[46] The standard exercise recommendation is a daily minimum of 30 minutes of moderate-intensity physical activity that is practical to perform. Larger weight loss goals are more appropriate for the more profoundly obese individuals who are contemplating surgical interventions. Even with surgery, ideal weight is hardly ever achieved, and after a number of years at a plateau, weight gain often recurs. In some patients, especially in the presence of severe comorbidities, simple prevention of additional weight gain may be the most reasonable goal.

Beyond the beneficial effects of therapeutic lifestyle change, specific intervention may be required to treat the dyslipidemia and hypertension associated with obesity and metabolic syndrome.[47] Most commonly, patients with metabolic syndrome have elevated triglyceride levels and low HDL cholesterol levels. Many patients receive statin therapy as the treatment of choice when low-density lipoprotein (LDL) cholesterol levels are excessive. Statins reduce cardiovascular disease risk in patients with type 2 diabetes and metabolic syndrome. Ezetimibe, which selectively inhibits intestinal cholesterol absorption, can be combined with statin therapy to further reduce LDL cholesterol by 15% to 20%. Fibrates effectively decrease triglyceride levels while increasing HDL cholesterol. Fibrates lower LDL cholesterol levels mildly, but when combined with statin therapy, fibrates may increase the risk of myopathy. Omega-3 fatty acids decrease triglyceride levels and improve insulin resistance in patients with metabolic syndrome. They are often used in combination therapy with other classes of the hypolipidemic drugs. Nicotinic acid is highly effective in raising HDL cholesterol levels in patients with metabolic syndrome. Nicotinic acid decreases the concentration of small, dense LDL particles and also lowers serum levels of lipoprotein (a).[47]

Dietary salt restriction and therapeutic lifestyle change are the primary means to address hypertension in obesity and metabolic syndrome. According to the 2017 guidelines published by the American College of Cardiology and American Heart Association (ACC/AHA),[48] patients having arterial blood pressure higher than 130/80 mm Hg may require antihypertensive drug therapy. There is no specific antihypertensive drug that is recommended as a first-line treatment in these patients, and generally the goal of antihypertensive therapy requires that polypharmacy be employed. A considerable element of the risk reduction resulting from antihypertensive therapy is decreasing arterial blood pressure.

The treatment of insulin resistance and hyperglycemia in metabolic syndrome, type 2 diabetes, and obesity is usually achieved with oral hypoglycemic drugs.[47] A number of different drug groups (and drugs within each group) that work through various mechanisms of action are available to treat hyperglycemia. These include α-glucosidase inhibitors, sulfonylureas, meglitinides, D-phenylalanine derivatives, biguanides, and thiazolidinediones.[47] Anesthetic implications include the need to assess and treat abnormal blood glucose levels in the perioperative period while being especially careful in the use of insulin in patients who are both insulin resistant and temporarily unable to continue on oral medication. At present, the optimal anesthetic management of patients who are taking metformin is not clear. There is a serious potential for postoperative lactic acidosis that can develop in patients using this drug. This possibility has led some physicians to routinely cancel or delay surgical procedures if metformin has been ingested within 48 hours of the scheduled surgery. Other physicians, however, have their patients continue taking metformin, both before and after surgery, without interruption if possible. Recent evidence indicates that patients taking metformin have a reduced risk for complications. It appears that metformin may be safely used in the perioperative period.[49]

Patients with metabolic syndrome and obesity may also be prescribed antiplatelet therapy. The AHA recommends that low-dose aspirin be used as a form of primary prevention in patients with metabolic syndrome whose 10-year risk for cardiovascular disease is 10% or greater as determined by Framingham risk scoring.

BEHAVIORAL INTERVENTIONS AND MODIFICATION

Behavioral interventions and behavioral modification are essential for obese patients to change their learned habits related to eating and physical activity in order to produce weight loss and long-term weight reduction.[47] This applies both for nonsurgical and surgical approaches to weight loss. The key features of typical behavioral programs include self-monitoring, goal setting, nutrition and exercise education, stimulus control, problem solving, cognitive restructuring, and relapse prevention. Patients often benefit from referral to multidisciplinary weight loss programs that incorporate diet, physical activity, and behavioral interventions to achieve their weight loss goals because these combined interventions provide the best weight loss and weight maintenance results without pharmacologic or surgical intervention. However, it is essential to identify and treat patients with eating disorders or major psychiatric disorders who require specialized psychiatric and psychological treatment to achieve meaningful weight loss.

PHARMACOTHERAPY FOR WEIGHT LOSS

Recommendations for pharmacotherapy as a treatment of obesity, first and foremost, stress lifestyle and behavioral modifications as the initial approaches to initiate weight loss.[27] Patients who do not reach their established reasonable weight loss goals by a combination of diet and exercise may be directed to pharmacotherapy to increase weight loss. There are weight loss drugs that have been approved by the Food and Drug Administration (FDA) and are currently prescribed for long-term use. These are typically used adjunctively with diet and exercise for patients having a BMI of 30 or greater (≥27 for patients with obesity-related risk factors or comorbid diseases). In current practice, there are only two categories of weight loss drugs: appetite suppressants and lipase inhibitors. Three drugs are currently available for the specific indication of weight loss: phentermine, lorcaserin,[50] and orlistat.[47] Phentermine, an adrenergic reuptake inhibitor, augments adrenergic signaling within the central nervous system and peripheral tissues. Phentermine decreases appetite and food intake and increases resting metabolic rate to promote weight loss. Its side effects include tachycardia and hypertension. Lorcaserin is a selective 5-HT$_{2C}$ receptor agonist that reduces food intake through the activation of pro-opiomelanocortin. Due to its selectiveness for the 5-HT$_{2C}$ receptor, lorcaserin has a better safety profile than the previous serotonin agonists for weight loss that have since been removed from the U.S. market due to increased risk of stroke and acute coronary syndrome. Lorcaserin should not be used in patients on selective serotonin reuptake inhibitors (SSRIs) or monoamine oxidase inhibitors (MAOIs) due to the risk of serotonin syndrome, which can be life threatening. Orlistat, a lipase inhibitor, reversibly binds to lipase and prevents both absorption and digestion of certain dietary fats. Because orlistat also interferes with the absorption of fat-soluble vitamins, patients using this drug need to supplement fat-soluble vitamins A, D, E, and K. It has significant gastrointestinal side effects including diarrhea, steatorrhea, flatulence, fecal incontinence, and oily rectal discharge.

ALTERNATIVE PHARMACOLOGIC OPTIONS

Allison and colleagues [51] reviewed the literature on dietary and herbal medications for weight loss. These agents are marketed as "food supplements," thereby escaping the purview of the FDA. Even though these supplements cannot legally claim to treat a disease, they can claim to reduce the risk of a disease. According to the review, claims for weight loss have been made for multiple products such as chitosan, chromium picolinate, conjugated linoleic acid, ephedra alkaloids (ma huang),[52] and *Garcinia cambogia*. [51] Most of the reports involving these compounds are from poor quality studies without any randomization, control groups, or blinding, thereby placing in question both efficacy and safety of these compounds. The only studies involving herbals that have consistently demonstrated weight loss involve combinations of ephedrine and caffeine.[53-54] Pharmacologically, this is expected because ephedrine, an adrenergic agonist, is known to be an appetite suppressant and a thermogenic agent. For this reason, *ma huang*, a natural source of the ephedra alkaloid, is added to most, if not all, dietary supplements marketed for weight loss. The success of ephedrine as a weight loss agent in combination with caffeine and or aspirin is well established. Unfortunately, multiple cases of cardiac and neurological issues, including hypertension, stroke, seizure, and even death have been reported,[55] possibly related to the inconsistent doses in the preparations and the lack of medical supervision in people consuming these products for weight loss. Consequently, the National Institutes of Health has banned these products from any recommended weight loss regimen.

IMPLANTED ELECTRICAL STIMULATORS

Implantable gastric stimulators are subcutaneously placed devices that resemble cardiac pacemakers and stimulate along the lesser curvature of the stomach. These gastric stimulators have been tried since the early 2000s and have been found to cause modest weight loss with few side effects.[56-57] Numerous clinical trials conducted in the United States and Europe have shown some promising results. Most studies demonstrated weight loss during the first 12 months; however only a few studies had a follow-up period of longer than 1 year.[58] One study documented a 25% excess weight loss, improved response to oral glucose tolerance test, decreases in arterial blood pressure, and an improvement in symptoms of gastroesophageal reflux disease (GERD), along with an increased parasympathetic drive. No serious side effects were noted in the first 65 patients reported on in this study[56] or in the 20 patients followed in another.[57] Ghrelin levels may play a role in the success of these devices.

Surgical Management of Obesity

Adult obesity is clearly rooted in childhood obesity. Unfortunately, pediatric obesity is the most common childhood nutritional disorder in the United States. This is one of the tragedies of the current obesity epidemic: the significant and increasing prevalence of obesity in the young. It has attained a level of controversy that has involved the placement of vending machines in schools and the availability of sweetened snacks and soft drinks in public places as public policy is developed to help control the epidemic of pediatric obesity. The diagnosis of pediatric obesity is commonly defined using criteria developed by the Centers for Disease Control and Prevention (CDC) using BMI-, age-, and sex-specific clinical growth charts.[59] These percentile curves apply to the ages of 2 to 20 years, and because BMI exhibits nonlinear variation during growth, percentile ranges are utilized. The CDC defines children possessing BMIs in the 5th to 85th percentiles as having "healthy weight." Children whose BMI is in the 85th to 95th percentile are "at risk for overweight," while those having a BMI above the 95th percentile are classified as "overweight." These classifications were previously regarded as "overweight" and "obese," respectively. This switch in terminology continues to be a source of confusion. Exceeding the 99th percentile is referred to as extreme pediatric obesity.

The National Health and Nutrition Examination Survey 2011–14 data show that the prevalence of obesity in children for age 2 to 5, 6 to 11, and 12 to 19 years are 9.4%, 17.4%, and 20.6%, respectively.[60] There does not appear to be an influence of gender on the prevalence of obese children above the age of 6 years. While the prevalence of obesity among children of ages 6 to 11 and 12 to 19 has steadily increased since 1988, there has been a slight recent decline in obesity among ages 2 to 5 years. A number of developing countries have childhood prevalence rates higher than that of the United States,[61] indicating that adolescent obesity is becoming pervasive.

Treatment of pediatric obesity is based on the balance of caloric intake and expenditure. These lifestyle changes are most successful with family intervention and support. The three pillars of success in this treatment are: better eating habits, increased physical activity, and decreased sedentary activity.[62] Success involves more than education of child and family; it incorporates goal setting, self-monitoring, incentives, and stimulus control. Lifestyle interventions remain the treatment of choice in pediatric obesity, but concomitant pharmacotherapy may be beneficial in some patients. Orlistat, which is covered elsewhere in this chapter, should be considered as second-line therapy for pediatric obesity.[63]

Although in 2000, less than 1% of all bariatric surgery patients in the United States were younger than 20 years of age,[64] the total number continues to increase. More adolescents are presenting for weight loss surgery, after failing to reduce weight and/or comorbidities in medically supervised and pharmacologically assisted weight loss programs. Even though many adult bariatric surgery programs are well qualified to provide safe and effective perioperative care for these patients, they may not be as well equipped to handle the unique metabolic and psychological needs of teenagers. Because of the shorter duration of obesity and fewer age-related comorbidities, adolescent patients have shorter length of stay and lower immediate postoperative mortality when compared to adults.[64]

Consent is an important issue in this population. Is parental consent to a semi-elective, relatively high-risk procedure appropriate? Does the child really understand the concept of high risk of death in the month after surgery? These and other such questions of ethics in medicine need to be addressed, but are beyond the scope of this chapter.

The rapid increase in the prevalence of both morbid obesity and superobesity, together with the increased risk of early demise within the obese population, has significantly increased the number of bariatric surgical procedures performed annually. The term bariatric surgery refers to surgical alteration of the small intestine or stomach with a view toward producing weight loss. It is estimated that over 216,000 bariatric surgeries are being performed annually in the United States. Care of obese patients is not limited to obesity surgery, however, as these patients present for all types of operations. Nonetheless, the benefits of surgical treatment of obesity now appear to have clear endocrinologic and cardiovascular value for reversing pathophysiologic effects of metabolic syndrome, type 2 diabetes, and other comorbidities of obesity, in addition to providing a mechanical means of enhancing weight loss.[65-71] Several alternative procedures in bariatric surgery have evolved from early procedures based on creating malabsorptive gut pathways to newer procedures aimed at altering hormonal regulation of caloric intake drive and satiety.[72] Primarily the available options can be separated into one of two groups: (1) operative procedures and (2) minimally invasive procedures that combine gastric restriction with induction of nutrient malabsorption.

OPERATIVE PROCEDURES

Surgery for obesity is one of the fastest growing surgeries performed worldwide.[73] The operative group can be divided into gastric restrictive procedures and procedures that combine gastric restriction with induction of nutrient malabsorption.[74-83] These procedures can be performed using an open, laparoscopic, or robot-assisted approach. In general, minimally invasive (laparoscopic, robotic) approaches are preferred over an open procedure as they have a lower complication rate, hospital stay, and morbidity.[84] The rate of open bariatric procedures has continued to decrease steadily to the extent that nearly 90% of surgical bariatric cases are now performed laparoscopically.[85]

RESTRICTIVE PROCEDURES

The surgical goal of restrictive operative procedures is to reduce and limit the patient's food intake capacity.[80] This is most commonly achieved by reducing the stomach's reservoir capacity. The vertical band gastroplasty was a widely practiced restrictive procedure in the previous three decades, but it was replaced by the minimally invasive laparoscopic gastric band procedure (LGB), which was very popular. However, in recent years, the percentage of bariatric procedures represented by LGB surgery performed has also decreased from 35% in 2011 to approximately 3% in 2016.[86] This decline in LGB operations is probably secondary to only modest amount of weight loss and high rates of band revisions and adjustments required. Recently, the sleeve gastrectomy (SG) has become

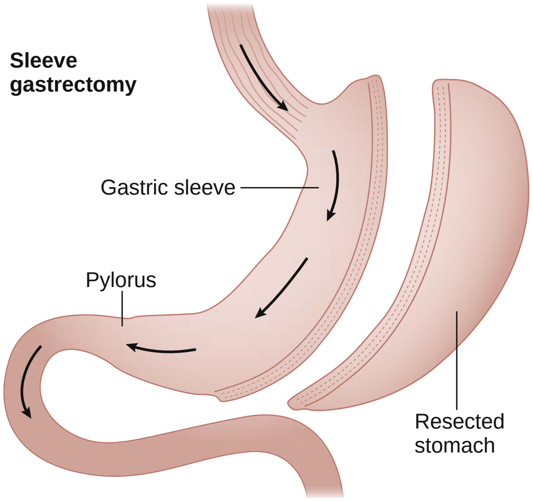

Fig. 58.2 Sleeve gastrectomy: a tubular stomach is created as the fundus and greater curvature of the stomach are removed around a 32F to 40F bougie.

the most commonly performed surgery for obesity. As illustrated in Fig. 58.2, in SG surgery, a tubular stomach is created around a 32 to 40 French bougie by removing the greater curvature of the stomach. The SG has been shown to be safe and effective, with a mean excess weight loss of approximately 65%.[87] The weight loss noted after a SG is not only due to the restrictive stomach, but also due to the decrease in hormonal level of ghrelin that regulates appetite and food intake.[88]

MALABSORPTIVE PROCEDURES

The surgical goal of malabsorptive procedures is to cause weight loss both by gastric restriction and nutrient malabsorption. Historically, early surgical procedures involved creation of a long jejunoileal bypass. Patients achieved significant weight reduction but this was commonly accompanied by an unacceptable incidence of serious vitamin and protein malabsorption, osteoporosis, and hepatic failure.

Today, gastric bypass (GBP), which is illustrated in Fig. 58.3, and biliary pancreatic diversion (BPD) are the two most commonly performed malabsorptive operations, and both have achieved success in safety and efficacy.[80] GBP is more commonly performed than BPD, and it is considered the safer of the two malabsorption procedures. GBP surgery involves the creation of a small gastric pouch by stapling or banding the stomach. This results in an element of gastric restriction. GBP also involves the creation of a Roux-en-Y anastomosis, in which the small gastric pouch is directly connected to the middle portion of the jejunum.[89] The OrVil device, shown along with nontapered and tapered bougies in Fig. 58.4, may be used by the surgeon to assist with creation of the anastomosis. The orogastric portion of the OrVil device is passed through the oropharynx and then pulled through by the surgeon via a gastrostomy, until the anvil portion of the OrVil device reaches the stomach. It is then attached to a stapler to create the anastomosis. The path for food through the gastrointestinal tract subsequently bypasses the gastric remnant and the upper portion of the duodenum. This procedure can be performed with a laparotomy incision or by using laparoscopic techniques.[90-91]

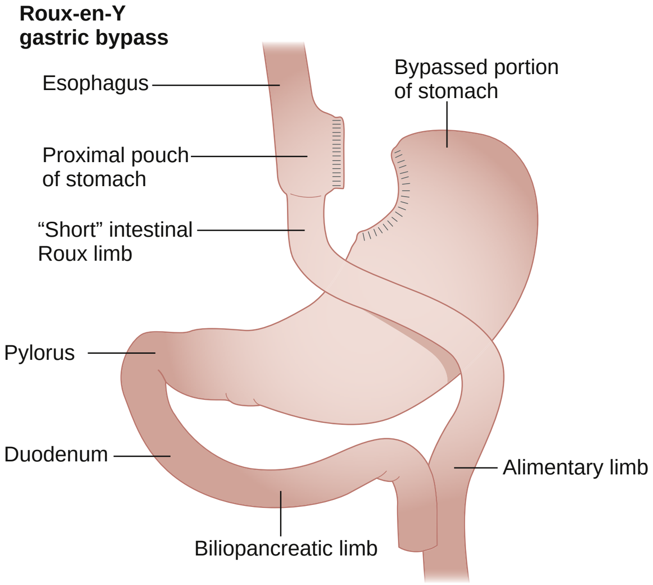

Fig. 58.3 Roux-en-Y gastric bypass: part of the stomach is detached from the rest, creating a small pouch. The pouch is connected to a lower part of the small intestine by a piece of small intestine, resembling a Y. As a result, parts of the stomach and small intestine are bypassed. However, digestive juices (bile acids and pancreatic enzymes) can still mix with the food, enabling the body to absorb vitamins and minerals and reducing the risk of nutritional deficiencies.

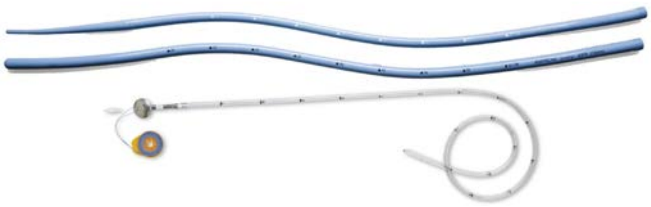

Fig. 58.4 32F tapered bougie *(top)*, 40F nontapered bougie *(middle)*, and OrVil device *(bottom)* commonly used during bariatric surgery.

Although this is considered to be a safe operation, the associated perioperative mortality is higher than that of restrictive procedures.[77] Additionally, there are some important long-term complications such as vitamin B_{12} deficiency, anemia, incisional hernia, cholelithiasis, and staple line failure that occur with significant frequency. Often a cholecystectomy is performed concurrently to prevent future cholelithiasis.[92] BPD is also a form of Roux-en-Y GBP reconstructive alimentary anatomy in which the bypassed intestinal segment includes the portion of duodenum at the point of entry of biliary and pancreatic secretions. This allows the bypassed intestine to be exposed to bile and pancreatic juice. The antrum is removed to avoid peptic ulceration, and food intake is only affected to a limited degree. The essential element of this operation is division of the small intestine about midlength, with the distal end of the alimentary limb being anastomosed to a generous gastric remnant. The more proximal biliopancreatic limb is anastomosed to the alimentary limb about 50 cm from the ileocecal valve. Following either the GBP or BPD form of operation, patients require life-long follow-up and may need micronutrient replacement long term.

MINIMALLY INVASIVE PROCEDURES

There have recently been a few devices approved in the United States for weight loss. One such device is the intragastric balloon that acts in a restrictive manner.[93] The intragastric balloon is placed in the patient's stomach endoscopically and is filled with saline to provide a sensation of fullness and satiety. The device can be kept in the patient's stomach for a maximum of 6 months and has been shown to decrease weight by an average of 6.8%. Most common complications of the intragastric balloon are related to gastrointestinal symptoms such as nausea, vomiting, halitosis, GERD, and abdominal discomfort; however serious complications such as balloon rupture, migration, and intestinal obstruction are possible.[94]

Another device that has been approved for use in the United States is an endoscopically placed percutaneous gastrostomy tube to facilitate stomach emptying. The device can be used for draining ingested foods and in preliminary studies has been shown to decrease total body weight (TBW) by approximately 12%.[95] The most common side effects were abdominal discomfort and peristomal irritation; however serious complications such as abdominal pain requiring hospitalization and peritonitis were noted infrequently.

HEALTH BENEFITS OF BARIATRIC SURGERY

The two most significant outcome measures of bariatric surgical success are weight loss and resolution of comorbidities. Major effects of bariatric operations have been nicely summarized in extensive meta-analyses[67,96-97] as well as in a major literature review.[98] Patients undergoing bariatric surgery with either SG or GBP have lost 52% to 68% of their excess weight.[99-100] This magnitude of weight loss is far greater than what is commonly achievable by nonsurgical methods, and it is considerably closer to patients' desired and expected weight loss. Long-term maintenance of weight loss of this magnitude can also be maintained for well over a decade.

Improvement in obesity-related and metabolic syndrome-related comorbidities have also been evaluated.[67,97-98,101] One clinical study demonstrated that at 1 year, type 2 diabetes remission rate with bariatric surgery was approximately 40% compared to 12% with medical treatment.[102] Another study showed remission rate at 2 years of approximately 85% compared to 0% with medical treatment.[103] This benefit seems to persist long-term as well, as at 6 years 62% of surgical patients experienced remission in their type 2 diabetes.[104] Resolution of diabetes following surgery is inversely related to the preoperative duration of the disease and occurs more in those patients having diabetes controlled using oral hypoglycemic agents. This clearly distinguishes surgical treatment of obesity as an important endocrinologic intervention, especially since the modest improvement in diabetes management that is produced by nonsurgical weight loss is accompanied by relapsing disease by nearly 100% of patients within 5 years.

Surgical effects on hypertension and hyperlipidemia are similarly impressive. A study of almost 1900 patients demonstrated that at a 6.5 year follow-up, 32% of surgically treated patients had remission of their hypertension versus 12.5% in medically managed patients.[105] A significant decrease in triglyceride levels, approximately 30% to 40% postbariatric surgery versus 8% from medical therapy; and increase in HDL cholesterol levels, 30% postsurgery versus 7% from medical therapy, have also been noted at 5 years.[106] Resolution of OSAHS seems to be independent of the specific bariatric surgical procedure employed, with resolution occurring overall in 85.7% of patients.[107] Postsurgical improvement in other comorbidities has also been demonstrated, with improvement in fatty infiltration of the liver, GERD symptoms, in respiratory function and asthmatic symptoms, reversal of the cardiomyopathy of obesity, and improvements in joint pain and mobility all having been reported.[71,108-112] The reduction in obesity-related comorbidities has been shown to endure with 5-year follow-up.[113] Although bariatric surgery has been shown to provide greater weight loss when compared with nonsurgical lifestyle interventions, comorbidities do resolve and risk factors do improve similarly with successful conservative treatments.[101]

Anesthetic Management of the Bariatric Surgical Patient

Patients undergoing bariatric surgery are receiving what is now the best long-term treatment for morbid obesity. However, their presurgical state is an agglomeration of abnormal physiologic conditions involving multiple organ systems. For that reason, there are considerable risks of mortality and morbidity associated with all types of bariatric surgery. Preoperative risk stratification can be used to identify patients at highest risk for significant morbid or fatal events when having bariatric surgery[114]; however detailed planning of the anesthesia care for the perioperative, intraoperative, and postoperative phases must be pursued for purposes of patient safety.

PREOPERATIVE EVALUATION

The preoperative assessment for anesthesia should include consideration of hypertension, diabetes, heart failure, and obesity hypoventilation syndrome. Results of the sleep study that the patient underwent are important. An AHI score greater than 30, implying severe sleep apnea, is a warning sign and a predictor for rapid and severe desaturation at induction. CPAP levels greater than 10 imply a patient with the potential for difficult mask ventilation.

Another useful piece of information in the preoperative evaluation is gleaned by examining the history of prior surgeries, their anesthetic challenges (i.e., ease or difficulty in securing the airway, intravenous access), need for intensive care unit admission, surgical outcomes, and the weight of the patient at that time. This information may either help ease some concerns or allow for better preparation for the upcoming anesthetic care. Recommended preoperative laboratory evaluations include fasting blood glucose, lipid profile, and serum chemistries (evaluating renal and hepatic function), complete blood count, ferritin, vitamin B_{12}, thyrotropin, and 25-hydroxyvitamin D.

If appropriately evaluated, ideally prepared, and optimally managed perioperatively, even patients with well-known coronary artery disease (CAD) have comparable morbidity and mortality as those without CAD.[115] The effect of OSA on perioperative risk remains controversial,[116] but most patients are screened for OSA using overnight oximetry or polysomnography, or both, if appropriate. If identified with OSA and recommended for CPAP, then patients are encouraged to initiate therapy at home and it should be continued throughout the perioperative period.

Liver function abnormalities are common in this patient population, especially nonalcoholic fatty liver disease, with the extent of disease a determining factor for perioperative risk and postoperative outcomes. Cirrhotic liver disease with portal hypertension may be considered a contraindication to bariatric surgery.[116] Gastrointestinal symptoms of dyspepsia may indicate the presence of *Helicobacter pylori*, which requires treatment by standard medical regimen.

The factors that may be considered contraindications for bariatric surgery include unstable CAD, uncontrolled severe OSA, uncontrolled psychiatric disorder, intellectual disability (IQ <60), inability to understand the surgery, perceived inability to adhere to postoperative restrictions, continued drug abuse, and malignancy with a poor 5-year survival prognosis. In most situations preoperative management of the medical morbidities can help optimize risk and convert high-risk patients to ones of acceptable risk.

The anesthetic care of patients with OSA is complicated by the side effects of anesthetic drugs on an already compromised respiratory system. The commonly presented comorbidities in this patient population only accentuate the problem.[117] The change in perioperative risk based on the anesthetic agent utilized is only deduced from anecdotal reports of different cases. There is a paucity of trials to definitively determine an optimal anesthetic regimen. Nevertheless, the American Society of Anesthesiologists and the Society for Anesthesia and Sleep Medicine have both published statements based on existing literature and consensus of expert opinion addressing the perioperative identification and management of patients who carry a formal diagnosis of OSA as well as for those who are at risk for sleep apnea but remain undiagnosed. Additional questions commonly arise and cannot yet be answered on the basis of high-grade scientific evidence: is it safe to perform procedures in patients with sleep apnea and treat them as outpatients or day surgery patients? What procedures pose sufficient risk to the patient to recommend an overnight hospital stay? Does narcotic use impact this decision? Would the increased role of nonsteroidal antiinflammatory drugs (NSAIDs) change these recommendations? Factors such as neck size and open versus laparoscopic surgery are being studied as to their impact on outcomes. Further research on these and other patient safety related questions is continuing.

INTRAOPERATIVE CARE

Obese patients present special intraoperative challenges for the anesthesiologist in airway management, positioning, monitoring, choice of anesthetic technique and anesthetic drugs, pain control, and fluid management. Many of these issues are equally important in their postoperative care. The most significant and best studied are airway management, including endotracheal intubation, pulmonary physiology, and techniques of maintaining adequate blood oxygenation and lung volume. Specific interventions, techniques, and approaches employed by the anesthesia care team providing anesthesia for obese patients are important determinants of outcomes.

Patient Positioning

Even though there are no evidence-based studies that demonstrate that obese patients have more frequent complications from positioning, it seems fairly intuitive that morbidly obese patients do require extra care in positioning (see also Chapter 34). Even in the supine position, rhabdomyolysis from pressure on gluteal muscles leading to renal failure[118] and death[119] have been reported. For obese patients placed in the prone position, cushioning gel pads or other weight-bearing rolls may have excessive weight placed on them. Pressure points must be checked carefully, and even though pressure sites may be carefully padded, skin breakdown can still occur. This may cause tissue necrosis and infections, especially in lengthy surgery.[120] It is difficult to protect the dependent hip from pressure effects with patients placed in lateral decubitus position. Obese patients have excess axillary tissue that may make it impossible or unnecessary to place a traditional axillary roll in this position. In the lithotomy position the challenge may be in supporting the weight of the patient's legs using regular, and not oversized, stirrups. To minimize the risk of tissue compression injury or development of compartment syndrome, the duration during which legs are held in stirrups should be held as short as possible.[121]

Airway Management

No positioning issue is more important than that regarding positioning of the obese individual for laryngoscopy and endotracheal intubation. These are often considered to be much more difficult to perform in obese patients than patients having a normal BMI. Difficulty with laryngoscopy and intubation is usually thought to result from the obese patient having a short, thick neck, large tongue, and significant redundant pharyngeal soft tissue. However, the correlation between morbid obesity and difficult laryngoscopy and intubation is not universally observed in clinical practice. This is likely to result from a simple, but important approach to clinical care, with careful attention being paid to patient positioning prior to induction of general anesthesia. Appropriate positioning plays an important role in providing optimal conditions for successful placement of the endotracheal tube under direct vision.

A number of studies have been conducted to determine the incidence of difficult laryngoscopy or intubation in the obese population, with mixed findings. One study found an association between oropharyngeal Mallampati classification and BMI as predictors of difficult laryngoscopy.[122] During laryngoscopy, the patients' heads were placed in optimum sniffing position, regardless of BMI. In a study conducted exclusively with obese patients, BMI was not found to be associated with intubation difficulties.[41] A high Mallampati score was identified as a predictor of "potential intubation problems," but intubation by direct laryngoscopy was successful in 99 of 100 patients studied. All patients were positioned with pillows or towels under their shoulders, with the head elevated and neck extended.

Another group studied both lean and obese patients and found a Mallampati score of III or IV to be the only independent risk factor for difficult intubation in the obese study group.[123] The authors demonstrated that the Mallampati score had low specificity and low positive predictive values (62% and 29%, respectively) for difficult intubation. They concluded that intubation was more difficult in the obese patients. During intubation, patients were placed in a semirecumbent position (30-degree elevation) with the head in the sniffing position. In another study ultrasound was used to quantify the amount of soft tissue between the skin and the anterior aspect of the trachea at the level of vocal cords.[124] The authors also assessed the airway by measurement of thyromental distance, mouth opening, degree of neck mobility, Mallampati score, neck circumference, and presence of OSA. Only an abundance of pretracheal soft tissue measured ultrasonically and neck circumferences were found to be positive predictors of difficult intubation with laryngoscopy performed with patients in the sniffing position. A meta-analysis of 35 studies was conducted to determine the diagnostic accuracy of preinduction tests for predicting difficult intubation in patients having no airway pathology.[125] The incidence of difficult intubation in obese patients was three times the incidence compared to the nonobese population. This may have resulted from suboptimal patient positioning, which was not clearly described in any of the preceding studies, including ramped positioning or elevating the upper body and head of morbidly obese patients to align the ear with the sternum horizontally, as has been shown to improve laryngoscopic view.[126] In this study, morbidly obese patients were assigned either to be in sniffing position or ramped position for airway management. The study demonstrated a statistically significant difference in laryngeal view, with ramped position providing the superior view. In one study, morbidly obese patients in a ramped position with a Mallampati score of III or IV and male gender were shown to predict possible difficult intubation, while no relationship was noted between difficult direct laryngoscopy and the presence of OSA, patient neck circumference, or BMI.[127]

Based on the evidence from randomized controlled trials and other literature on airway management of obese patients, patients should be readily intubated by direct laryngoscopy if placed carefully in ramped position. This can be achieved using commercially available positioning devices[128] or by building a ramp from blankets or sheets to achieve the desired placement of the patient's head relative to the thorax.[129] Obese patients must be examined for the common objective signs of potential difficult intubation, which include small mouth opening, large protuberant teeth, limited neck mobility, and retrognathia. Alternative airway management techniques include the use of a video laryngoscope for intubating obese patients.[130] Compared to direct laryngoscopy, the use of video laryngoscopy in patients undergoing bariatric surgery has shown to provide a better glottic view and decreased time required to successfully intubate the trachea.[131] Performance of an awake, topicalized direct laryngoscopy with modest sedation can also be utilized to assess laryngoscopic view in deciding whether to proceed with induction of general anesthesia or awake, sedated fiberoptic intubation. Of course, the equipment for emergency airway management including laryngeal masks and a fiberoptic bronchoscope should be immediately available.

Another area that requires specific attention during the perioperative period is the obese patient's pulmonary physiology. It is especially important to appreciate techniques to maintain oxygenation and lung volume in caring for the obese patient. First, obese patients have multiple pulmonary abnormalities, including decreased vital capacity, inspiratory capacity, expiratory reserve volume, and functional residual capacity. Second, closing capacity in obese individuals is close to or may fall within tidal breathing, particularly in the supine or recumbent position. Moreover, both lung and respiratory system compliance are low with obesity because patients breathe at lung volumes that are abnormally low.[132] As a result of the underlying physiology, the obese patient is likely to undergo rapid oxygen desaturation, particularly during periods of apnea such as occurs during induction of general anesthesia. However, the presence of OSA by itself does not independently increase the risk of the patient desaturating during induction of general anesthesia as long as appropriate precautions are instituted.[133] However, after induction and intubation have occurred, patients may continue to derecruit gas exchange units throughout the anesthetic course.[134] A variety of maneuvers have been studied to preserve oxygenation and maintain lung volume specifically in the obese population.

In one study of the rate of development of hypoxemia in patients during apnea, patients received 100% oxygen by facemask to achieve denitrogenation before induction of general anesthesia.[134] The apneic period was continued after induction until the SpO_2 fell to 90%. Obese patients reached the end point in less than 3 minutes, whereas it took 6 minutes in patients having a normal BMI. Efforts to prevent atelectasis formation and desaturation during induction of general anesthesia in obese individuals include application of CPAP during preoxygenation,[135-137] and mask application of positive end-expiratory pressure (PEEP), and mechanical ventilation following induction.[137] Use of 10 cm H_2O CPAP during preoxygenation in the supine position resulted in a higher partial pressure of oxygen (PaO_2) after intubation and decreased the amount of atelectasis that developed.[81] The combination of CPAP during preoxygenation and PEEP/mechanical ventilation after induction significantly increased the nonhypoxemic apnea duration from 2 minutes, found in controls not receiving CPAP or PEEP, to 3 minutes. Use of 7.5 cm H_2O CPAP during 3 minutes of preoxygenation while supine, however, did not change the time required for obese patients to desaturate to an SpO_2 of 90%.[136] Preoxygenation using 25-degree head-up (back inclined) as opposed to supine positioning without positive airway pressure did increase the elapsed time needed for anesthetized, apneic, obese individuals to desaturate to an SpO_2 of 92%.[138] The patients in head-up position had a significantly higher PaO_2 after preoxygenation, just prior to induction. The obesity-associated gas exchange defect depended on the waist-to-hip ratio, an index of the distribution of adipose tissue surrounding the thorax.[139] This study further demonstrated that morbidly obese men are more likely to have poorer pulmonary gas exchange than morbidly obese women. In a study conducted to assess the relationship between patient positioning and development of hypoxemia in obese patients during apnea after anesthetic induction and intubation, patients were ventilated with a 50% oxygen/50% air mixture for 5 minutes before the ventilator circuit was disconnected.[140] Apnea was continued until the SpO_2 fell to 92%, at which time ventilation was resumed. Patients in the supine position reached the end point in 2 minutes, but it took 30 seconds longer if supine position with the back elevated 30-degrees was used and 1 minute longer if 30-degree reverse Trendelenburg position was used. Use of 30-degree reverse Trendelenburg position in obese patients undergoing bariatric surgery was also shown to reduce the alveolar-to-arterial oxygen difference, as well as increase total ventilatory compliance and reduce peak and plateau airway pressures when compared to supine position.[141] Vital capacity has also been shown to decrease to a greater extent under general anesthesia in obese patients compared to normal weight patients.[142]

A variety of intraoperative maneuvers to maintain lung volume and oxygenation have also been studied. Increasing tidal volume incrementally from 13 to 22 mL/kg in obese patients ventilated under general anesthesia did not improve the gas exchange defect but did increase airway pressures.[143] Use of 10 cm H_2O PEEP has been demonstrated to have a greater effect in obese patients compared to normal subjects on improving ventilatory mechanics, increasing PaO_2, and decreasing alveolar-to-arterial oxygen difference during general anesthesia with neuromuscular blockade.[144] In addition to PEEP alone, use of a recruitment maneuver such as sustained lung inflation to 55 cm H_2O for 10 seconds followed by application of PEEP has been demonstrated to prevent atelectasis from developing and to improve oxygenation, whereas neither PEEP nor a recruitment maneuver alone achieved the same degree of maintenance of pulmonary function.[145]

Pneumoperitoneum during laparoscopic procedures increases pulmonary resistance and decreases dynamic lung compliance.[146] During pneumoperitoneum, alterations in body position, tidal volume, and respiratory rate had no effect on the alveolar-to-arterial oxygen difference in obese patients.[147] During pneumoperitoneum for laparoscopic bariatric surgery, alveolar recruitment by repeated sustained lung inflation to 50 cm H_2O followed by mechanical ventilation with 12 cm H_2O PEEP has been shown to increase PaO_2 intraoperatively, however at the expense of causing hypotension that required vasopressor use.[148] In an attempt to optimize PEEP in obese patients undergoing laparoscopic surgery, a normal functional residual capacity was maintained with 15 ± 1 cm H_2O PEEP. Infusion of intravascular volume expanders was required to prevent PEEP-induced hemodynamic compromise.[149]

In summary, a back-up position with the use of PEEP during preoxygenation at induction of anesthesia and intraoperatively has been shown to decrease the A-a gradient in an obese patient.[150] Furthermore, the application of noninvasive modes of ventilation including pressure support and bilevel delivered by mask for preoxygenation, induction, and maintenance of anesthesia to maintain oxygenation and ventilatory mechanics in obese patients has been shown to be beneficial. Ideal patient positioning, use of PEEP, and special modes of ventilation just prior to emergence and extubation may help maintain pulmonary function and gas exchange postextubation. Currently there are no published guidelines to address the issues of maintenance of oxygenation and ventilatory mechanics in obese patients undergoing general anesthesia. Considering both the airway management issues detailed previously as well as the oxygenation, lung volume, and ventilatory mechanics issues described above for obese individuals, anesthesia care providers should position patients to achieve the combined goals of providing a superior laryngoscopic view for ease of endotracheal intubation while establishing optimal conditions for oxygenation and preservation of pulmonary mechanical function.

It is the practice at our institution that obese patients are initially placed in a ramped position and then into reverse Trendelenburg, if needed, to achieve a 25- to 30-degree incline of the thorax prior to preoxygenation. Patients are then preoxygenated for 3 to 5 minutes using 100% oxygen delivered under positive pressure. For those patients receiving CPAP at home for OSA, we use CPAP or pressure support ventilation by facemask at a pressure level identical to the patient's home CPAP setting. Otherwise, CPAP of 8 to 10 cm H_2O is appropriate. Following induction, it is reasonable to maintain 8 to 10 cm H_2O PEEP intraoperatively, but care must be taken to treat any hypotension that may occur. Finally, if the patient's position must be changed intraoperatively, one must return the patient to head-up position prior to emergence and extubation.

In preparation for emergence from anesthesia, neuromuscular blockade must be fully reversed before the patient is extubated. Given the advent of a pressure support ventilation mode on many newer models of anesthesia machines, the bariatric patient can be maintained on pressure support during emergence once spontaneous ventilation has resumed. When adequate muscle strength has returned, as demonstrated by sustained tetanus using the nerve stimulator and performance of a 5-second head lift, the awake patient who is following commands can be extubated. Pressure support or CPAP can be delivered immediately by mask applied to the face as is done during preoxygenation prior to induction of anesthesia. The use of PEEP and noninvasive modes of ventilation just after emergence and extubation has been shown to improve pulmonary function in patients up to 24 hours later.[151] We utilize CPAP during recovery, especially in those patients already prescribed CPAP for their OSA. The basic premise that must be respected with regard to airway management and its integral relationship to pulmonary function is that morbid obesity incurs significant derangements of lung function and pulmonary mechanics. These factors must be managed carefully in order to minimize intraoperative and postoperative pulmonary complications.[152,153]

Anesthetic Drugs and Dosing

Anesthetic drugs such as opioids, propofol, and benzodiazepines are all well known to have exaggerated responses in patients with OSA. They may decrease pharyngeal musculature tone, which is essential in maintaining airway patency.[40,154] In the setting of OSA, volatile agents are known to diminish ventilatory response to carbon dioxide, especially in children with tonsillar hypertrophy. Another pediatric study showed that spontaneously breathing intubated children with a history of OSA have depressed ventilation and half have apnea with 0.5 μg/kg of intravenous fentanyl. Although these data are from the pediatric literature, it would be prudent to apply the same principles in obese adult patients until proven otherwise. It therefore becomes attractive to use short-acting drugs and nondepressors of ventilation like the α_2-agonist dexmedetomidine. This should, at least in theory, speed up the return to baseline respiratory function.[120]

Commonly used anesthetic drugs can be dosed on TBW or IBW based on lipid solubility. In the past, IBW was interpreted to mean fat-free weight, implying that it could be used as a substitute for lean body weight or more correctly, lean body mass (LBM), usually approximated as 120% of IBW. LBM is a good weight approximation to use when dosing hydrophilic medications. As expected, volume of distribution (V_D) is changed in obese patients with regard to lipophilic drugs. This is especially true of benzodiazepines and barbiturates, among the commonly used anesthetic drugs. Two exceptions to this rule are procainamide[155] and remifentanil,[156] which even though highly lipophilic, have no relationship between properties of the drug and their V_D.[157] Consequently, commonly used anesthetic drug dosing is based on IBW for propofol, vecuronium, rocuronium, sugammadex, and remifentanil. In contrast, midazolam, succinylcholine, cisatracurium, fentanyl, and sufentanil should be dosed on the basis of TBW. Another caveat to this recommendation is that maintenance doses of propofol should be based on TBW and conversely for sufentanil on IBW.[157] This implies that one can use, based on patient weight, larger amounts of benzodiazepines, fentanyl, or sufentanil, although these are best titrated to desired clinical effect. Conversely, based on real body weight, smaller amounts of propofol are needed to anesthetize the patient.

With vecuronium or rocuronium, the initial dose should be based on IBW with additional doses based on the closely followed state of neuromuscular blockade. Complete blockade in the morbidly obese patient is necessary not just for the surgeon's convenience, but also to facilitate mechanical ventilation. The drug chosen is not as important as the depth of the state of paralysis. The pharmacokinetic profile of sugammadex is similar to that of rocuronium, and its dosing should be based on IBW.[158]

Volatile anesthetics are chosen based on physical characteristics of tissue solubility which are expressed as blood-gas partition coefficients and fat-blood partition coefficients. There is some evidence to suggest that desflurane may be the anesthetic of choice based on consistent and rapid recovery profile versus sevoflurane and propofol.[159,160] Some studies suggest that the differences in immediate recovery between sevoflurane and desflurane are not clinically significant.[161]

Even though nitrous oxide provides some analgesic effect and is rapidly eliminated, we prefer to avoid it based on the high oxygen demands in the obese. Its entry into air spaces in short intraabdominal surgeries may not be a significant factor, but in bariatric surgery, especially when done laparoscopically or robotically, any increase in bowel gas volume could make a challenging surgical procedure even more difficult for the surgeon.

Induction of Anesthesia

There has been considerable debate regarding obesity, the risk of aspiration of gastric contents, and the need to provide aspiration prophylaxis.[162] Abdominal bloating or fullness and female sex are associated with delayed gastric emptying of solids and liquids in diabetic patients.[163] Although many obese patients have type 2 diabetes, separate studies of gastroesophageal reflux during anesthesia have not demonstrated body habitus to be a predictor of reflux rates.[164] Gastric fluid volume and pH have been shown to be the same in obese patients who are fasting or who have oral intake of up to 300 mL of clear liquid 2 hours prior to being anesthetized.[165] Obesity itself does not increase aspiration risk. However, acid aspiration prophylaxis including H_2–receptor agonists or proton pump inhibitors must be considered in patients having identifiable aspiration risks. Rapid sequence induction or awake fiberoptic intubation may also be considered in such patients.[40]

Based on experience from obstetric practice, there is a body of evidence to show that regional anesthesia, especially epidural and spinal, are safe and feasible in patients with large body habitus.[120] However, regional anesthesia is technically more difficult due to the physical challenge of placing the catheters and the tendency of these catheters to migrate out of the epidural space. Special equipment, including longer needles or special ultrasound probes, may be needed for the correct placement of catheters in these patients. Care should be exercised in dosing these catheters because of the increased cephalad spread of the drug and the block due to the smaller epidural space compared to normal-weight patients.[166,167] The degree of respiratory compromise suffered by obese patients will also be of a larger magnitude than normal-weight patients with a high regional block.

There is little evidence to suggest that epidural pain management improves overall outcomes. Since the trend of laparoscopic surgery is increasing compared to open laparotomies, this becomes less of an issue. In the morbidly obese patient who is having an open laparotomy, use of a thoracic epidural catheter to control pain has the most important benefit of reducing the attenuation of vital capacity postoperatively.[168]

Obesity per se does not require invasive monitoring, so GBP surgery can be performed safely with routine monitoring. The indications for invasive monitoring stem from the comorbidities present in these patients. Since these tend to run together in the patients needing surgery, the incidence of invasive monitoring in these patients thereby increases.[169] Morbidly obese patients having serious comorbidities such as obesity-hypoventilation syndrome, who present with pulmonary hypertension and cor pulmonale, may require a pulmonary artery catheter or intraoperative evaluation utilizing transesophageal echocardiography. The rationale for central venous access may stem from difficulties in peripheral access rather than any other indication. Many patients receive an inferior vena cava filter prophylactically due to the high risk of deep vein thrombosis and pulmonary embolism associated with obesity and bariatric surgery.[170] It is recommended that a central line inserted at the time of surgery should be placed under ultrasound guidance to decrease complications as well as to increase ease of placement. Similarly, difficulty in noninvasive blood pressure measurements, secondary to body habitus–related difficulty in appropriate cuff placement, may be an indication for arterial catheter placement. Obtaining arterial blood gases may help to guide intraoperative ventilation and extubation.

Postoperative pain management in weight loss surgery patients can involve intravenous analgesia employing patient-controlled analgesia (PCA) or thoracic epidural analgesia. There is no clear data proving the superiority of one technique over the other; therefore in many instances, surgical technique, open versus laparoscopic, may help guide that decision. In our practice, we tend to reserve epidural anesthesia for patients undergoing open GBP. Even with these drawbacks, we have approximately an 80% success rate with superobese patients. It may be prudent to test the effectiveness of the epidural prior to induction of anesthesia. An opioid-based PCA with local anesthetic wound infiltration and adjunct non-narcotics is a reasonable alternative approach for most patients. Injection of local anesthetic in the incision site prior to making the incision may result in preemptive analgesia. Adjunct analgesia with non-narcotic medications such as oral and intravenous acetaminophen, NSAIDs, low dose ketamine, and dexmedetomidine, will decrease opioid requirements and thereby opioid-induced side effects as well.

Intraoperatively, utilizing the appropriate operating room table for the patient's weight is critical since the consequences of having a table not rated to the patient's weight can have serious consequences for both patient and the operating room personnel. It may be useful to keep the patient strapped throughout the period of sedation and sleep. Along with a safety strap, it might also be useful to apply a bean bag under the patient to keep the patient from sliding off the operating room table. Thermal management in the operating room is best accomplished by forced-air warmers. Arm boards may need extra padding to keep the patient from having the arm and shoulder out of an anatomical position. If the arms are to be tucked by the side of the patient, then wide, well padded sleds may be useful.

Fluid requirements for the obese patient are larger than predicted for those of normal BMI and even during a relatively short, 2- to 3-hour case these patients may need 3 to 4 L of crystalloid fluid to prevent acute tubular necrosis (ATN) in the kidneys. Hypovolemia, which can cause a protracted prerenal state and contribute to the development of ATN, can be prevented by appropriate hydration. Retrospective data from the University of Pittsburgh Medical Center suggests that primary acute renal failure after weight loss surgery occurs in approximately 2% of patients. Other predisposing factors include BMI greater than 50 kg/m^2, prolonged surgical time, prior history of renal disease, and intraoperative hypotension.[171]

POSTOPERATIVE MANAGEMENT

In our practice, we prefer to have the postbariatric surgery patients stay at the same location consistently. This allows skilled nursing and ancillary care to be provided to patients on a consistent basis. These patients are kept on their CPAP or bilevel positive airway pressure machines as much as possible with monitoring of end-tidal carbon dioxide and SpO_2 by pulse oximetry recommended. Monitoring capnometry in the postoperative period is critical for assessing a morbidly obese patient's respiratory function since the administration of supplemental oxygen may delay the diagnosis of hypoventilation. At the Hospital of the University of Pennsylvania, patients identified as having difficult airways are distinguished with armbands, and with visible signs on their beds, their hospital charts, and on the electronic medical records for the remainder of their hospital stay. Additionally, a note by the attending anesthesiologist explaining the difficulty in intubation as well as the means utilized to secure the airway in the operating room is available in the room. In case of an unexpected emergency intubation, for whatever reason, we feel that this extra information is extremely useful to the resuscitation team.

Postoperative nausea and vomiting (PONV) is a common reason for delayed discharge from the postanesthesia care unit (PACU). Intraabdominal surgery is a known risk factor for PONV.[172] Patients undergoing bariatric surgery have significant manipulation of their stomach, which may increase their risk of PONV. It is recommended to include a multimodal approach to PONV prophylaxis, including ondansetron, dexamethasone, and placement of a scopolamine patch when not contraindicated in order to minimize patient dissatisfaction and serious complications such as aspiration or wound and anastomotic dehiscence.

Enhanced recovery after surgery (ERAS) protocols are being used widely in surgical patients to decrease morbidity and decrease in-hospital stay. One study looking at patients undergoing an SG demonstrated a median hospital stay of 1 day in the ERAS group compared to 2 days in the control group, without any difference in postoperative complications or readmissions.[173] The ERAS protocol included standardized preoperative patient education, shortened preoperative fasting, multimodal analgesia and antiemetic therapy, avoidance of fluid overload, early ambulation and feeding, and incentive spirometry.

MANAGEMENT OF COMPLICATIONS

Bariatric surgery is considered to be very safe, but not without potential complications, which are increasingly predictable.[174] In-hospital mortality rates for patients undergoing laparoscopic and open bariatric surgery are 0.17% and 0.79%, respectively.[175] Mortality is associated with a need for reoperation during the same hospitalization,[176] with intestinal leakage being a serious complication accounting for a large number of patient deaths.[177] Risk factors also include older age, excessive obesity, poor functional status, and comorbid conditions of congestive heart failure or renal failure.

Morbidity occurring during the immediate postoperative in-hospital period typically falls into one of four categories; wound, gastrointestinal, pulmonary, and cardiovascular complications. The complication rates are significantly lower in each category for patients undergoing laparoscopic rather than open procedures. The American College of Surgeons National Surgical Quality Improvement Program database showed that patients who had an open GBP compared with a laparoscopic GBP had a morbidity rate of 7.4% versus 3.4%, return visits to the operating room rate of 4.9% versus 3.6%, and median postoperative length of stay of 3 versus 2 days, respectively. Box 58.3 provides a categorical listing of complications of bariatric surgery.

The most common complications requiring reoperation include postoperative intraabdominal bleeding, anastomotic leakage, suture line dehiscence, small bowel obstruction, and deep wound infection,[177-182] all of which may

BOX 58.3 Complications of Bariatric Surgery

Early	Bleeding
	Infection
	Dehydration
	Peritonitis
	Leak from anastomotic site
	Bowel obstruction
	Perforation
	Pneumonia
	DVT/PE
	Death
Late	Anorexia
	Cholelithiasis/cholecystitis
	Pouch dilation or stricture
	Gastroesophageal reflux disease/dysphagia
	Herniation at surgical site
	Small bowel obstruction
	Marginal ulcers
	Pancreatitis
	Nutritional issues
	Fat-soluble vitamin deficiencies, especially vitamin B_{12}

require a general anesthetic for laparotomy. Despite deep vein thrombosis prophylaxis therapy in the perioperative period, patients can also present postoperatively with deep vein thrombosis or pulmonary embolism and require an anesthetic for placement of an inferior vena cava filter device. As mentioned earlier, prophylactic filters are often placed prior to bariatric surgery.[170] The risk of venous thromboembolism is higher in open bariatric procedures, men, and patients with preexisting lower extremity edema and pulmonary hypertension.[183]

In all cases requiring reoperation shortly after the original bariatric procedure it is prudent to review the anesthesia record. Specific attention should be paid to the documentation of patient position and technique employed for airway management in the prior anesthetic. Patients may be hypovolemic from blood loss, inadequate hydration, vasodilatation, and insensible fluid losses associated with fever and infection. It is especially important to consider additional or new risks of aspiration of gastric contents. This may be due to the presence of a postoperative ileus, small bowel obstruction, and surgical creation of a Roux-en-Y GBP limb that excludes the pylorus as an element of protection from reflux of intestinal contents. Decompression of the gastric pouch in patients going for surgery to relieve a small bowel obstruction can be achieved with careful introduction of a nasogastric or orogastric tube just prior to induction of general anesthesia. Although this may increase the risk of violating a fresh, competent anastomotic suture line, communication between anesthesiologist and surgeon can be pursued to determine the risks and benefits of performing this maneuver. During the ensuing laparotomy, any perforation of a fresh suture line resulting from the attempt to decompress the gastrointestinal tract can be repaired immediately and the nasogastric or orogastric tube can subsequently be left in place for continued postoperative drainage.

Depending on the extent of reoperation, requirement for volume resuscitation, blood transfusion, degree of peritonitis with anastomotic leak, presence of sepsis, or other significant continued risks to health, patients undergoing reoperation may require prolonged postoperative ventilation. Requirements for postoperative pain management may also be considerably different than those associated with the initial bariatric procedure. In patients who are sufficiently hemodynamically stable immediately prior to reoperation, an epidural catheter can be placed prior to induction for pain management as part of the postoperative care. This is especially valuable in obese patients undergoing laparotomy, as is described elsewhere in this chapter.

There are also a number of potential major complications requiring surgical intervention weeks, months, or even years after a bariatric surgical operation has been performed. Patients may develop anastomotic strictures or ulcers, ventral hernias, gastrogastric fistulae, and severe reflux disorders requiring additional surgery.[92] Small bowel obstruction may appear weeks after surgery.[181] Patients may desire cosmetic operations to remove excess skin or liposuction procedures to sculpt dysmorphic body areas following significant weight loss. Patients may also require adjustment of a gastric band or pursue band removal. The anesthetic considerations for such patients should include a review of the prior anesthetic record to glean information regarding airway and pain management. The degree of weight loss achieved and the resolution of comorbidities including diabetes, hypertension, and OSA may significantly alter the approach used in the bariatric operation.

A fraction of patients develop significant neurologic complications following GBP surgery.[184-186] These are known to include polyneuropathy, polyradiculoneuropathy, myelopathy, encephalopathy, and optic neuropathy. Myelopathy occurs most frequently but does not present until about 10 years after surgery.[184] These patients have demonstrable nutritional deficiencies, but except for the vitamin B_{12} and copper deficiencies found in patients with myelopathy, no specific nutritional profile has been found to correlate with neurological complications. Although neurologic symptoms accompanying weight loss surgery are not likely to result in additional surgery, they represent new or additional comorbidities that should be fully considered by the anesthesiologist caring for patients having previously undergone bariatric surgery.

The nutritional and metabolic complications of bariatric surgery also include protein and protein-calorie malnutrition. Patients may have excessive weight loss occurring either too rapidly or beyond the predetermined goals, steatorrhea or severe diarrhea, hypoalbuminemia, marasmus, edema, and hyperphagia.[92,187-189] In cases of severe malnutrition, patients may require enteral or parenteral nutrition therapy. Surgical revision may be required to correct excessive weight loss and hypoalbuminemia. Under such circumstances, an anesthetic regimen accounting for decreased drug binding effects of a low serum albumin must be considered.

Considerations for Management of the Obese Patient Presenting for Nonbariatric Surgery

Few studies have evaluated the importance of morbidity when performing common nonbariatric surgical procedures on the obese patient. A study by Dindo and coworkers[190] of 6336 patients did not find any difference in the incidence or severity of complications after elective general surgery, except surgical site infections. Other studies have assessed the effect of obesity on wound infections and have shown that they are increased.[191-192] Multiple studies have demonstrated that obese patients are at higher risk after gynecological, orthopedic, cardiovascular, urological, and transplantation surgery, while other studies have not shown there to be obesity-related risk differences.[193-194]

From the data of Dindo and associates[190] regarding complications and the type of surgical procedure, operative severity and open surgery were independent risk factors for postoperative complications. They found no differences in the type of postoperative complications in obese and nonobese groups. This study provides data to decrease the prejudice that patients with obesity are implied to have a higher incidence of postoperative complications. This preconception may pertain more to the perception of the medical team as a result of technical difficulties on the anesthetic and surgical end. Surgeries may last longer, about 25% more time for laparoscopic than for open cholecystectomy in the morbidly obese. Significantly, the wound infection rate was much better after laparoscopic than after open surgery, which supports the practice of performing laparoscopic surgery in obese patients rather than the alternative.

Anesthesia and the Renal and Genitourinary Systems

VINOD MALHOTRA, ANUJ MALHOTRA, ANUP PAMNANI, and
DANIEL GAINSBURG

KEY POINTS

- Innervation of the intraabdominal components of the genitourinary system—the kidney and the ureter—is primarily thoracolumbar (T8-L2). The nerve supply of the pelvic organs—the bladder, prostate, seminal vesicles, and urethra—is primarily lumbosacral with some lower thoracic input.
- The spinal level of pain conduction for the external genitourinary organs is S2-4, except for the testes (T10-L1).
- The kidneys receive 15% to 25% of the total cardiac output, with most of this blood directed to the renal cortex. Renal medullary papillae are more vulnerable to ischemic insults. Kidneys successfully autoregulate their blood flow between 60 and 160 mm Hg mean arterial pressures.
- The glomerular filtration rate (GFR) is the best measure of glomerular function. Creatinine clearance is a good measure of the GFR; urine output is not.
- Hypervolemia, acidemia, hyperkalemia, cardiorespiratory dysfunction, anemia, and bleeding disturbances are manifestations of chronic renal failure.
- Serum creatinine, most commonly used as a marker of renal function, has several limitations. Newer biomarkers, such as serum cystatin C, are better and earlier measures of acute kidney injury and the risk of end-stage renal disease, as well as related mortality.
- Although renal transplantation reverses most of the abnormalities in end-stage renal disease, dialysis improves only some and introduces additional complications of its own.
- Newer techniques, such as laser prostatectomy, are making transurethral resection of the prostate (TURP) syndrome a rare event. TURP syndrome is a constellation of symptoms caused by the absorption of hypotonic bladder irrigants. Cardiovascular and neurologic changes are due to hypoosmolality, hyponatremia, hyperglycinemia, hyperammonemia, and hypervolemia.
- Regional anesthesia offers several advantages over general anesthesia for standard, but not laser, TURP. Yet, 30-day mortality rates remain unchanged at 0.2% to 0.8%.
- Laparoscopic surgery in urology frequently requires insufflation of carbon dioxide into the retroperitoneal space. In lengthy procedures, pneumomediastinum and subcutaneous emphysema of the head and neck may occur.
- Extracorporeal shock wave lithotripsy (ESWL) historically caused significant physiologic changes related to immersion in a water bath, but newer generations have eliminated the water bath and hence those risks. Shock waves can cause clinically insignificant dysrhythmias. Pregnancy and untreated bleeding disorders are contraindications to ESWL.
- Regarding renal tumors, 5% to 10% extend into the renal vein, inferior vena cava, and right atrium. Complications ranging from circulatory failure to embolization of tumor during surgery may occur. Cardiopulmonary bypass may be necessary for surgery.
- Radical prostatectomy may cause significant blood loss, and intraoperative venous air emboli can occur. Regional anesthesia with spontaneous ventilation is associated with less blood loss than general anesthesia and intermittent positive pressure ventilation. Other advantages of epidural anesthesia include a decreased incidence of deep vein thrombosis and the initiation of preemptive analgesia. Whether outcomes are dependent on the choice of anesthesia is not clear.
- Robotic radical prostatectomy is associated with reduced blood loss and postoperative pain compared with open radical prostatectomy. Anesthetic concerns are related to steep head-down tilt and pneumoperitoneum and include hypercarbia, hypoxemia, increased intraocular and intracranial pressures, decreased perfusion pressure to lower extremities, and positional injuries.
- Anesthetic concerns of robotic-assisted surgery include the length of surgical time, intravenous fluid management, pneumoperitoneum, and positioning. The most frequent reported complications are peripheral neuropathies, corneal abrasions, vascular complications (including compartment syndrome, rhabdomyolysis, and thromboembolic disease), and the effects of edema.
- Postoperative urinary retention should be considered as a source of postoperative pain after urologic surgery. Prompt diagnosis, either clinically or with ultrasound, and bladder catheterization if indicated (postvoid residual >600 mL) is effective and can prevent sequelae.

Patients requiring anesthesia for renal and genitourinary surgery are frequently at the extremes of age. In addition to the physiologic changes of aging in older patients, concomitant cardiovascular and respiratory comorbidity is common. A medical history, physical examination, and appropriate laboratory tests are necessary to evaluate concomitant disease. In pediatric urologic patients, a careful history should exclude other nonurologic congenital lesions.

Urologic procedures are performed mostly on the kidneys, adrenals, ureters, urinary bladder, prostate, urethra, penis, scrotum, testis, and spermatic cord. Because their sensory nerve supply is primarily thoracolumbar and sacral outflow (Table 59.1), these structures are well adapted for regional anesthesia.

Innervation of the Genitourinary System

The parts of the genitourinary system that are in the abdomen receive their nerve supply from the autonomic nervous system by means of sympathetic and parasympathetic pathways. The pelvic urinary organs and genitalia are supplied by somatic and autonomic nerves. Table 59.1 summarizes the pain conduction pathways and spinal levels of the genitourinary system.

KIDNEY AND ABDOMINAL URETER

Sympathetic nerves to the kidney originate as preganglionic fibers from the eighth thoracic through the first lumbar segments and converge at the celiac plexus and aorticorenal ganglia (Fig. 59.1). Postganglionic fibers to the kidney arise mainly from the celiac and aorticorenal ganglia. Some sympathetic fibers may reach the kidney via the splanchnic nerves. Parasympathetic input is from the vagus nerve.[1] Sympathetic fibers to the ureter originate from the tenth thoracic through the second lumbar segments and synapse with postganglionic fibers in the aorticorenal and superior and inferior hypogastric plexuses. Parasympathetic input is from the second through fourth sacral spinal segments.[1] Nociceptive fibers travel along the sympathetics to the same spinal segments. Pain from the kidney and ureter is referred mainly to the somatic distribution of the tenth thoracic through the second lumbar segments—the lower part of the back, flank, ilioinguinal region, and scrotum or labia. Effective neural block of these segments is necessary to provide adequate analgesia or anesthesia.

BLADDER AND URETHRA

Sympathetic nerves to the bladder and urethra originate from the eleventh thoracic to the second lumbar segments, travel through the superior hypogastric plexus, and supply the bladder through the right and the left hypogastric nerves.[2] Parasympathetic nerves arise from the second through the fourth sacral segments and form the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. Vesical branches proceed toward the bladder base, where they provide the nerve supply to the bladder and proximal part of the urethra (Fig. 59.2). Parasympathetic fibers are the main motor supply to the bladder (with the exception of the trigone) and far outnumber sympathetic fibers in the bladder.[2]

TABLE 59.1 Pain Conduction Pathways and Spinal Segment Projection of Pain of the Genitourinary System

Organ	Sympathetics, Spinal Segments	Parasympathetics	Spinal Levels of Pain Conduction
Kidney	T8-L1	CN X (vagus)	T10-L1
Ureter	T10-L2	S2-4	T10-L2

Fig. 59.2 (A) Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. (B) Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. *Solid lines* indicate preganglionic fibers; *dashed lines* indicate postganglionic fibers; and *dotted lines* indicate sensory fibers. (From Gee WF, Ansell JF. Pelvic and perineal pain of urologic origin. In: Bonica JJ, ed. *The Management of Pain*. 2nd ed. Philadelphia: Lea & Febiger; 1990:1368–1378.)

The afferents carrying sensations of stretch and fullness of the bladder are parasympathetic, whereas pain, touch, and temperature sensations are carried by sympathetic nerves. Sympathetic fibers are predominantly α-adrenergic in the bladder base and urethra, and β-adrenergic in the bladder dome and lateral wall. Knowledge of these aspects of neuroanatomy is important to appreciate the pharmacologic effects on the urologic system of neural ablation or regional block and drugs with adrenergic or cholinergic effects.[2]

PROSTATE AND PROSTATIC URETHRA

The prostate and the prostatic urethra receive sympathetic and parasympathetic supply from the prostatic plexus arising from the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. The spinal origin of the nerve supply is primarily lumbosacral (see Fig. 59.2).[2]

PENIS AND SCROTUM

The autonomic supply to the penile urethra and the cavernous tissue comes from the prostatic plexus. Somatic fibers from the pudendal nerve (S2-4) supply the external sphincter. The dorsal nerve of the penis, the first branch of the pudendal nerve, is its main sensory supply. The scrotum is innervated anteriorly by the ilioinguinal and genitofemoral nerves (L1 and L2) and posteriorly by perineal branches of the pudendal nerve (S2 and S4).[2]

TESTES

The testes descend from their intraabdominal location to the scrotum during fetal development. Because they share their embryologic origin with the kidney, their nerve supply is similar to that of the kidney and upper part of the ureter and extends up to the T10 spinal segment.[2]

Renal Blood Flow

The kidneys receive approximately 15% to 25% of total cardiac output, or 1 to 1.25 L/min of blood, through the renal arteries, depending on the state of the body. Most of the blood is received by the renal cortex, with only 5% of cardiac output flowing through the renal medulla, which makes the renal papillae vulnerable to ischemic insults. Renal blood flow is regulated by various mechanisms that control the activity of vascular smooth muscle and alter vascular resistance. Sympathetic tone of renal vessels increases during exercise to shunt renal blood flow to exercising skeletal muscle; similarly, renal blood vessels relax during the resting condition of the body. Sympathetic stimulation resulting from surgery can increase vascular resistance and reduce renal blood flow, whereas anesthetics may reduce renal blood flow by decreasing cardiac output.

Glomerular capillaries separate afferent arterioles from efferent arterioles. Glomerular capillaries are high-pressure systems, whereas peritubular capillaries are low-pressure systems. Consequently, the glomerular capillaries are a

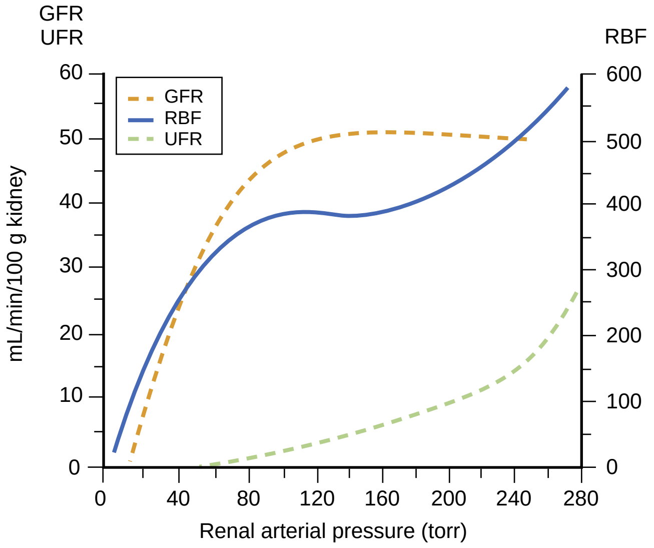

Fig. 59.3 Autoregulation of renal blood flow *(RBF)* and the glomerular filtration rate *(GFR)*. The relationships between RBF, GFR, and urine flow rate *(UFR)* and mean renal arterial pressure in dogs are shown as renal arterial pressure is varied from 20 to 280 mm Hg. Autoregulation of RBF and GFR is observed between approximately 80 and 180 mm Hg. (Redrawn from Hemmings HC. Anesthetics, adjuvants and drugs and the kidney. In: Malhotra V, ed. *Anesthesia for Renal and Genitourinary Surgery*. New York: McGraw-Hill; 1996;18.)

fluid-filtering system, whereas the peritubular capillaries are a fluid-absorbing system. The vasa recta, a specialized portion of peritubular capillaries formed from efferent arterioles, are important in the formation of concentrated urine by a countercurrent mechanism. An intrinsic mechanism that causes vasodilation and vasoconstriction of renal afferent arterioles regulates the autoregulation of renal blood flow. A decrease in mean arterial pressure also decreases renal blood flow and eventually affects the glomerular filtration rate (GFR) when the pressure decreases to less than 60 mm Hg. A persistently low mean arterial pressure greater than 60 mm Hg affects renal blood flow but does not affect the GFR because of the intrinsic mechanism of autoregulation (Fig. 59.3). Autoregulation maintains mean arterial pressure between 60 and 160 mm Hg in intact and denervated kidneys.[3]

Although knowledge of neuroanatomy and renal blood flow is essential to provide adequate anesthesia, a thorough understanding of renal physiology and pharmacology is equally important. Genitourinary surgical patients frequently have mechanical or functional renal disease. Anesthetics and surgery can significantly alter renal function. Conversely, renal dysfunction significantly affects the pharmacokinetics and pharmacodynamics of anesthetics and adjuvant drugs. Evaluation of a patient with renal disease is discussed later.

Anesthesia for Patients With Renal Disease

EVALUATION OF RENAL FUNCTION

Renal disease can be discovered incidentally during a routine medical evaluation, or patients may exhibit evidence of renal dysfunction, such as hypertension, edema, nausea, and hematuria. The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases, this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the GFR. The history and physical examination, although equally important, are variable among renal syndromes; specific symptoms and signs are discussed in sections on each disease entity. Further diagnostic categorization is based on anatomic distribution: prerenal disease, postrenal disease, and intrinsic renal disease. Intrinsic renal disease can be divided further into glomerular, tubular, interstitial, and vascular abnormalities. Laboratory tests useful in evaluating renal function are described next (Table 59.2).

TABLE 59.2 Commonly Ordered Renal Function Tests

Test Name	Reference Range	Units
Urea nitrogen	5-25	mg/dL
Creatinine	0.5-1.5	mg/dL
Sodium	133-147	mmol/L
Potassium	3.2-5.2	mmol/L

GLOMERULAR FUNCTION

Glomerular Filtration Rate

The GFR is the best measure of glomerular function. Normal GFR is approximately 125 mL/min. However, manifestations of reduced GFR are not seen until the GFR has decreased to 50% of normal. When GFR decreases to 30% of normal, a stage of moderate renal insufficiency ensues.

TABLE 59.3 Clinical Abnormalities in Chronic Renal Failure and Their Response to Dialysis and Erythropoietin Treatment

Improved by Dialysis	Improved by Adding Erythropoietin	Variable Response	Not Improved	Develop After Dialysis Therapy
Volume expansion and contraction	Fatigue	Secondary hyperparathyroidism	Increased lipoprotein level	Adynamic osteomalacia
Hypernatremia and hyponatremia	Impaired mentation	Hyperuricemia	Decreased high-density lipoprotein level	β_2-Microglobulinemia
Hyperkalemia and hypokalemia	Lethargy	Hypertriglyceridemia	Impaired growth and development	Muscle cramps
Metabolic acidosis	Pallor	Protein-calorie malnutrition	Infertility and sexual dysfunction	Dialysis dysequilibrium syndrome
Hyperphosphatemia	Anemia	Headache	Amenorrhea	Hypotension and arrhythmias
Hypocalcemia	Bleeding diathesis	Peripheral neuropathy	Sleep disorders	Hepatitis
Vitamin D–deficient osteomalacia		Restless legs syndrome	Pruritus	Idiopathic ascites
Carbohydrate intolerance		Paralysis	Lymphocytopenia	Peritonitis
Hypothermia		Seizures	Splenomegaly and hypersplenism	Leukopenia
Asterixis		Myopathy		Hypocomplementemia
Muscular irritability		Arterial hypertension		
Myoclonus		Cardiomyopathy		
Coma		Accelerated atherosclerosis		
Congestive heart failure or pulmonary edema		Vascular calcification		
Pericarditis		Hyperpigmentation		
Uremic lung		Peptic ulcer		
Ecchymoses		Gastrointestinal bleeding		
Uremic frost		Increased susceptibility to infection		
Anorexia				
Nausea and vomiting				
Uremic fetor				
Gastroenteritis				

Patients remain asymptomatic with only biochemical evidence of a decline in GFR (i.e., an increase in serum concentrations of urea and creatinine). Further workup usually reveals other abnormalities, such as nocturia, anemia, loss of energy, decreasing appetite, and abnormalities in calcium and phosphorus metabolism.

As the GFR decreases further, a stage of severe renal insufficiency begins. This stage is characterized by profound clinical manifestations of uremia and biochemical abnormalities, such as acidemia; volume overload; and neurologic, cardiac, and respiratory manifestations. At the stages of mild and moderate renal insufficiency, intercurrent clinical stress may compromise renal function further and induce signs and symptoms of overt uremia. When the GFR is 5% to 10% of normal, it is called end-stage renal disease (ESRD), and continued survival without renal replacement therapy becomes impossible (Table 59.3).

Blood Urea Nitrogen

The blood urea nitrogen (BUN) concentration is not a direct correlate of reduced GFR. BUN is influenced by nonrenal variables, such as exercise, bleeding, steroids, and massive tissue breakdown. The more important factor is that BUN is not elevated in kidney disease until the GFR is reduced to almost 75% of normal.[1]

Creatinine and Creatinine Clearance

Measurements of creatinine provide valuable information regarding general kidney function. Creatinine in serum results from turnover of muscle tissue and depends on daily dietary intake of protein. Normal values are 0.5 to 1.5 mg/100 mL; values of 0.5 to 1 mg/100 mL are present during pregnancy. Creatinine is freely filtered at the glomerulus, and apart from an almost negligible increase in content because of secretion in the distal nephron, it is neither reabsorbed nor secreted. Serum creatinine measurements reflect glomerular function (Fig. 59.4),[4] and creatinine clearance is a specific measure of GFR. Creatinine clearance can be calculated by the following formula derived by Cockcroft-Gault that accounts for age-related decreases in GFR, body weight, and sex:

$$\begin{aligned}&\text{Creatinine clearance (mL/min)} = \\ &\quad[(140 - \text{Age}) \times \text{Lean body weight (kg)}]\,/ \\ &\quad[\text{Plasma creatinine (mg/dL)} \times 72]\end{aligned}$$

This value should be multiplied by 0.85 for women because a lower fraction of body weight is composed of muscle.

Because there is such a wide range in normal values, a 50% increase in serum creatinine concentration, indicative of a 50% reduction in GFR, may go undetected unless baseline values are known. In addition, excretion of drugs dependent on glomerular filtration may be significantly decreased despite what might seem to be only slightly elevated serum creatinine values (1.5-2.5 mg/100 mL). The serum creatinine concentration and clearance are better indicators of general kidney function and GFR than are similar measurements of urea nitrogen (Box 59.1). However, there are disease states in which even the serum creatinine can be affected independent of the GFR (Table 59.4). The main limitation of current GFR estimates is the greater inaccuracy in populations without known chronic kidney disease than in those with the disease. Nonetheless, current GFR estimates facilitate detection, evaluation, and management of the disease, and they should result in improved patient care and better clinical outcomes.[5]

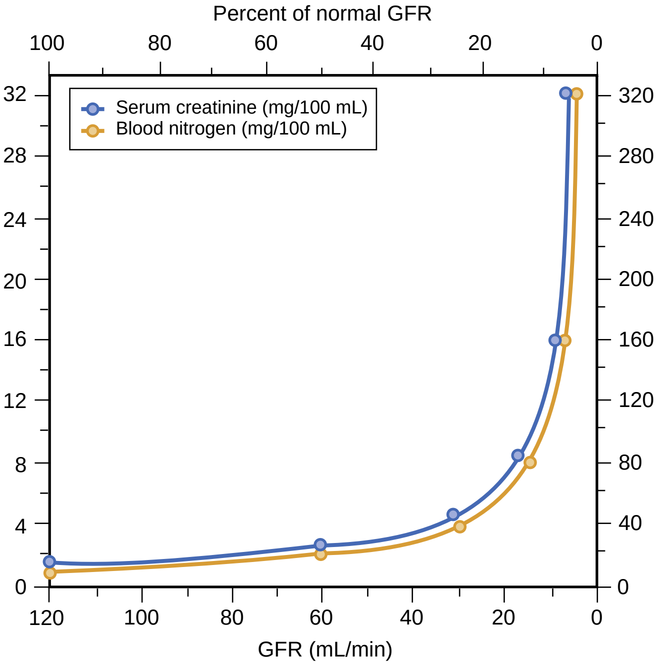

Fig. 59.4 **Theoretic relationship between blood urea nitrogen and creatinine versus glomerular filtration rate *(GFR)*.** (Redrawn from Kassirer JP. Clinical evaluation of kidney function-glomerular function. *N Engl J Med*. 1971;285:385.)

BOX 59.1 Conditions Affecting Blood Urea Nitrogen Independently of Glomerular Filtration Rate

Increased Blood Urea Nitrogen

- Reduced effective circulating blood volume (prerenal azotemia)
- Catabolic states (gastrointestinal bleeding, corticosteroid use)
- High-protein diets
- Tetracycline

Decreased Blood Urea Nitrogen

- Liver disease
- Malnutrition
- Sickle cell anemia
- Syndrome of inappropriate secretion of antidiuretic hormone

TUBULAR FUNCTION

Concentration

Urinary specific gravity is an index of the kidney's concentrating ability, specifically renal tubular function. Determination of urinary osmolality (i.e., measurement of the number of moles of solute [osmoles] per kilogram of solvent) is a similar, more specific test. Excretion of concentrated urine (specific gravity, 1.030; 1050 mOsm/kg) is indicative of excellent tubular function, whereas a urinary osmolality fixed at that of plasma (specific gravity 1.010; 290 mOsm/kg) indicates renal disease. The urinary dilution mechanism persists after concentrating defects are present, so a urinary osmolality of 50 to 100 mOsm/kg still may be consistent with advanced renal disease.

TABLE 59.4 Conditions Affecting Serum Creatinine Independently of Glomerular Filtration Rate

Condition	Mechanism
CONDITIONS CAUSING ELEVATION	
Ketoacidosis	Noncreatinine chromogen
Cephalothin, cefoxitin	Noncreatinine chromogen
Flucytosine	Noncreatinine chromogen
Other drugs—aspirin, cimetidine, probenecid, trimethoprim	Inhibition of tubular creatinine secretion
CONDITIONS CAUSING DECREASE	
Advanced age	Physiologic decrease in muscle mass
Cachexia	Pathologic decrease in muscle mass
Liver disease	Decreased hepatic creatine synthesis and cachexia

Protein

Patients without renal disease can excrete 150 mg of protein per day; greater amounts may be present after strenuous exercise or after standing for several hours. Massive proteinuria (i.e., >750 mg/day) is always abnormal and usually indicates severe glomerular damage.

Glucose

Glucose is freely filtered at the glomerulus and is subsequently reabsorbed in the proximal tubule. Glycosuria signifies that the ability of the renal tubules to reabsorb glucose has been exceeded by an abnormally heavy glucose load and is usually indicative of diabetes mellitus. Glycosuria also may be present in hospitalized patients without diabetes who are receiving intravenous glucose infusions.

ADDITIONAL DIAGNOSTIC TESTS

Urinalysis and Appearance

Gross and microscopic observations of urine and its sediment, along with determination of urinary pH, specific gravity, protein content, and glucose content, are two of the most readily available, inexpensive, and informative laboratory tests. The gross appearance of urine may indicate the presence of bleeding or infection in the genitourinary tract. Microscopic examination of urinary sediment may reveal casts, bacteria, and various cell forms, supplying diagnostic information in patients with renal disease.

Urine and Serum Electrolytes With Blood Gases

Sodium, potassium, chloride, and bicarbonate concentrations should be determined if impairment in renal function is suspected. However, the results of these tests usually remain normal until frank renal failure is present and hyperkalemia does not occur until patients are uremic. Measuring urinary sodium or chloride excretion is especially useful when attempting to differentiate between causes of hyponatremia, as seen in volume contraction (whether a decrease in total circulatory volume or a decrease in effective arterial blood volume), versus conditions associated with increased salt loss, such as the syndrome of inappropriate secretion of antidiuretic hormone, salt-losing nephropathy, or adrenal insufficiency.[6] If significant renal disease is present, patients consuming a diet high in animal protein may develop metabolic acidosis.

Novel Biomarkers of Renal Function. Although serum creatinine is most commonly used as a marker of GFR and hence renal function, it has some limitations in that it is influenced by nonrenal factors such as age, gender, muscle mass and metabolism, diet, and hydration. Furthermore, creatinine levels may take several hours or days to reach a steady state to accurately reflect the GFR as indicator of renal function in acute kidney injury (AKI). Several new markers of renal function have been identified. Serum cystatin C, a ubiquitous protein that is exclusively excreted by glomerular filtration, is less influenced by variations in muscle mass and nutrition than is creatinine. It may better predict risk of death and ESRD across diverse populations.[7]

Other novel biomarkers such as *N*-acetyl-β-D-glucosaminidase, kidney injury molecule-1, interleukin-18, uromodulin, and microRNA are also showing promise at early detection of kidney injury. These biomarkers may have a future role in reducing morbidity and mortality associated with kidney injury in the perioperative setting.[8]

Electrocardiogram. The electrocardiogram reflects the toxic effects of potassium excess more closely than determination of the serum potassium concentration.

Imaging Studies

Renal Ultrasound. Ultrasound is the most frequently used diagnostic examination for the evaluation of the kidneys and urinary tract. It is noninvasive, uses no ionizing radiation, and requires minimal patient preparation. It is the first-line examination in patients with renal dysfunction for assessing kidney size and the presence or absence of hydronephrosis and obstruction. It can be used to assess the vasculature of native and transplanted kidneys. Ultrasound is also used to evaluate renal structure and to characterize renal masses.[9]

Computed Tomography Scan of Kidneys. A stone protocol computed tomography (CT) scan of the kidneys, ureter, and bladder has become the study of choice for the detection of kidney stones because of its ability to detect stones of all kinds, including uric acid stones and nonobstructing stones in the ureter. Even in areas in which ultrasound is the first-line imaging modality, CT offers a complementary and sometimes superior means of imaging. Masses in the kidney can be evaluated using either contrast-enhanced CT or renal ultrasound.[9]

Computed Tomography Angiography. CT angiography is used for the evaluation of renal artery stenosis and is emerging rapidly as a useful diagnostic tool. Although it is comparable with magnetic resonance angiography (MRA) as a noninvasive study, it requires the use of iodinated contrast material, which may cause contrast media–induced nephropathy.[9]

Magnetic Resonance Imaging With Magnetic Resonance Angiography. Magnetic resonance imaging allows for detailed tissue characterization of the kidney and surrounding structures. It is a good alternative to contrast-enhanced CT, especially in patients who cannot tolerate iodinated contrast material and in patients for whom reduction of radiation exposure is desired, such as pregnant women and children. Gadolinium, a paramagnetic intravenous contrast agent, is used routinely in MRA because it improves lesion detection and diagnostic accuracy. It is generally well tolerated with a good safety profile. However, nephrogenic systemic fibrosis, a rare, multiorgan, fibrosing condition for which there is no known effective treatment, has been recognized to occur in patients with moderate to severe renal disease.[9]

IMPORTANT PATHOPHYSIOLOGIC MANIFESTATIONS OF CHRONIC RENAL FAILURE

Hypervolemia

Total body contents of sodium and water are increased in chronic renal failure (CRF),[6] although this increase might not be clinically apparent until the GFR is reduced to very low levels. Weight gain is usually associated with volume expansion and is offset by the concomitant loss of lean body mass. The combination of loop diuretics with metolazone, which acts by inhibiting the Na-Cl cotransporter of the distal convoluted tubule, can overcome diuretic resistance.

Acidemia

Although urine can be acidified normally in most patients with CRF, these patients have a reduced ability to produce ammonia. In the early stages, the accompanying organic anions are excreted in urine, and the metabolic acidosis is of the non–anion gap variety. With advanced renal failure, a fairly large “anion gap” can develop (to approximately 20 mmol/L), however, with a reciprocal decrease in plasma bicarbonate ion (HCO_3) concentration. This acidemia is usually corrected by hemodialysis. Although acidemia is well compensated in moderate CRF, patients can become acidemic and hyperkalemic[10] in the postoperative period (Table 59.5).

Hyperkalemia

The approximate daily filtered load of potassium (K^+) is 700 mmol. Most of this filtered load is reabsorbed in tubule segments, and most of the K^+ excreted in the final urine reflects events governing K^+ handling at the level of the cortical collecting tubule and beyond. K^+ excretion in the gastrointestinal tract is augmented in patients with CRF. However, hyperkalemia may be precipitated in numerous clinical situations, including protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells, metabolic acidosis, and exposure to various medications that inhibit K^+ entry into cells or K^+ secretion in the distal nephron.

Cardiac and Pulmonary Manifestations

Hypertension is a common complication of CRF and ESRD. Because hypervolemia is the major cause of hypertension in uremia, normotension is usually restored by the use of diuretics in predialysis patients or by dialysis in ESRD patients. However, despite therapy, patients remain hypertensive due to activation of the renin-angiotensin system and autonomic factor. Patients generally have left

TABLE 59.5 Metabolic Acidosis in Chronic Renal Failure

	$PaCO_2$ (mm Hg)	pH	HCO_3^-(mEq/L)	K^+ (mEq/L)
Preoperative	32	7.32	17	5
Intraoperative	40	7.25	18	5.3
Postoperative	44	7.21	19	5.6
	48	7.18	19	5.9

The patient is a 36-year-old man with severe diabetic nephropathy and end-stage renal failure undergoing cadaver renal transplantation. Preoperatively, the patient has a chronic metabolic acidosis (HCO^{3-}, 17 mEq/L) with partial respiratory compensation ($PaCO_2$, 32 mm Hg; pH 7.32). Potassium is high normal at 5 mEq/L. Intraoperatively, he is given "standard" mechanical minute ventilation, and with "normal" $PaCO_2$ (40 mm Hg), the metabolic acidosis is unmasked (pH 7.25), and potassium increases to 5.3 mEq/L. His trachea is extubated at the end of the procedure, but graft function is sluggish, and the metabolic acidosis remains unchanged. With residual opioid-induced narcosis, moderate CO_2 retention occurs ($PaCO_2$, 44 mm Hg and 48 mm Hg), pH decreases further to 7.18, and a dangerous degree of hyperkalemia develops (K^+, 5.9 mEq/L).

TABLE 59.6 Management Guidelines for Correction of Anemia of Chronic Renal Disease

ERYTHROPOIETIN	
Starting dosage	50-150 U/kg per week IV or SC (once, twice, or three times per week)
Target hemoglobin	11-12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4 wk
DARBEPOETIN ALFA	
Starting dosage	0.45 mg/kg administered as single IV or SC injection once weekly
	0.75 mg/kg administered as a single IV or SC injection once every 2 wk
Target hemoglobin	12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4-wk period
IRON	
Monitor iron stores by TSat and serum ferritin	
If patient is iron-deficient (TSat <20%; serum ferritin <100 g/L), administer iron, 50-100 mg IV twice per week for 5 wk; if iron indices are still low, repeat the same course	
If iron indices are normal but hemoglobin is still inadequate, administer IV iron as outlined above; monitor hemoglobin, TSat, and ferritin.	
Withhold iron therapy when TSat >50% or ferritin >800 ng/mL (>800 g/L)	

IV, Intravenous; *SC*, subcutaneous; *TSat*, percent transferrin saturation.

ventricular hypertrophy and accelerated atherosclerosis (disordered glucose and fat metabolism). Pericarditis can be observed in patients with inadequate dialysis unlike patients with CRF who undergo regular dialysis.

Pulmonary edema and restrictive pulmonary dysfunction are a common feature of patients in renal failure. Hypervolemia, heart failure, decreased serum oncotic pressure, and increased pulmonary capillary permeability contribute to the development of pulmonary edema. Diuretic therapy or dialysis can be effectively used to treat pulmonary congestion and edema due to excess intravascular volume.[11]

Hematologic Manifestations

CRF usually causes a normochromic, normocytic anemia. Anemia is generally observed when the GFR decreases to less than 30 mL/min and is due to insufficient production of erythropoietin by the diseased kidneys. Other factors are iron deficiency, either related to or independent of blood loss from repeated laboratory testing, blood retention in the dialyzer, or gastrointestinal bleeding.[12] Treatment of anemia with iron, darbepoetin alfa, and human recombinant erythropoietin (Table 59.6) restores a normal hematocrit and avoids repetitive red blood cell transfusions, reduces the requirement for hospitalization, and decreases cardiovascular mortality by approximately 30%.[13]

Prolongation of the bleeding time because of decreased activity of platelet factor 3, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption contributes to the clotting defects. The abnormality in platelet factor 3 correlates can be corrected with dialysis, although prolongation of the bleeding time can be observed in well-dialyzed patients. Abnormal bleeding times and coagulopathy in patients with renal failure may be managed with desmopressin, cryoprecipitate, conjugated estrogens, blood transfusions, and erythropoietin use.[9]

EFFECTS OF DRUGS IN PATIENTS WITH REDUCED RENAL FUNCTION

Most anesthetic drugs are weak electrolytes and are lipid soluble in the un-ionized state; they are extensively reabsorbed by renal tubular cells. Termination of their action does not depend on renal excretion; redistribution and metabolism produce this effect. After biotransformation, these drugs are excreted in urine as water-soluble, polar forms of the parent compound. They are usually pharmacologically inactive, and their retention is harmless. Drugs with prominent central and peripheral nervous system activity in this category include most narcotics, barbiturates, phenothiazines, butyrophenone derivatives, benzodiazepines, ketamine, and local anesthetics. However, several drugs are lipid insoluble or are highly ionized in the physiologic pH range and are eliminated unchanged in urine. Their duration of action may be extended in patients with impaired renal function. Drugs in this category include muscle relaxants, cholinesterase inhibitors, thiazide diuretics, digoxin, and many antibiotics (Table 59.7).[14]

Opioids

Renal failure has implications of major clinical importance with respect to the metabolism and excretion of morphine

TABLE 59.7 Drugs Used or Encountered in Anesthesia Practice that Significantly Depend on Renal Elimination

Completely Dependent	Partially Dependent
Digoxin, inotropes (used frequently; monitoring of blood levels indicated in chronic renal failure)	Intravenous anesthetics—barbiturates
Others—aminoglycosides, vancomycin, cephalosporins, and penicillins	Muscle relaxants—pancuronium
	Anticholinergics—atropine, glycopyrrolate
	Cholinesterase inhibitors—neostigmine, edrophonium
	Others—milrinone, hydralazine, cycloserine, sulfonamides, and chlorpropamide

and meperidine. For the fentanyl congeners, the clinical importance of renal failure is less marked.[15]

Morphine is an opioid with active metabolites that depend on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (morphine-3-glucuronide and morphine-6-glucuronide) are excreted via the kidney. The kidney also plays a role in the conjugation of morphine, accounting for nearly 40% of its metabolism.[16] Patients with renal failure can develop high levels of morphine-6-glucuronide and life-threatening respiratory depression. In view of these changes induced by renal failure, alternatives to morphine should be considered in patients with severely altered renal clearance mechanisms.[15]

The clinical pharmacology of meperidine is also significantly altered by renal failure. Normeperidine, the chief metabolite, has analgesic and central nervous system (CNS) excitatory effects. Because the active metabolites are subject to renal excretion, this potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure.[17]

The clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding potentially can alter the free fraction of the fentanyl class of opioids.[15] As with fentanyl, sufentanil pharmacokinetics are not altered in any consistent fashion by renal disease, although greater variability exists in the clearance and elimination half-life of sufentanil when patients have impaired renal function.[18] An increased clinical effect is likely with alfentanil in renal failure because of a decreased initial volume of distribution and an increased free fraction of alfentanil.[19] However, no delay in recovery after alfentanil administration should be expected. Neither the pharmacokinetics nor the pharmacodynamics of remifentanil are altered by impaired renal function.[20]

Hydromorphone, as the parent drug, does not substantially accumulate in hemodialysis patients. Conversely, an active metabolite, hydromorphone-3-glucuronide, quickly accumulates between dialysis treatments but seems to be effectively removed during hemodialysis.[21] With careful monitoring, hydromorphone can be used safely in patients who require dialysis. However, it should be used with caution in patients with a GFR less than 30 mL/min and who have yet to start dialysis or who have withdrawn from dialysis.

Inhaled Anesthetics

All inhaled anesthetics are biotransformed to some extent, with the nonvolatile products of metabolism eliminated almost entirely by the kidney.[22] Reversal of the CNS effects of inhaled anesthetics depends on pulmonary excretion; therefore impaired kidney function would not alter the response to these anesthetics. From the viewpoint of selecting an anesthetic that would not be harmful to patients with mild or moderate impairment of renal function, all of the modern potent inhaled vapor anesthetics are acceptable. Fluoride levels after isoflurane increase by only 3 to 5 μM[23] and by only 1 to 2 μM after halothane[24]; therefore these anesthetics have no nephrotoxic potential.

Desflurane and sevoflurane, two newer inhaled anesthetics, are remarkably different from each other with respect to their molecular stability and biotransformation. Desflurane is highly stable and resists degradation by soda lime[25] and the liver. The mean inorganic fluoride concentration after 1 minimum alveolar concentration (MAC)-hour exposure to desflurane was less than 1 μM.[26] The safety of desflurane in renal failure patients has been confirmed. In addition, more sensitive indices of renal function—urine retinol-binding protein and β-*N*-acetylglucosaminidase—showed no evidence of renal damage. Prolonged exposure to desflurane (7 MAC-hours) has been associated with normal renal function.[27]

Sevoflurane is not very stable. Soda lime causes it to decompose,[28] and it is biotransformed by the liver. Plasma inorganic fluoride concentrations approaching nephrotoxic levels (50 μmol/L)[29] have been reported after prolonged inhalation of sevoflurane. However, no evidence of gross changes in renal function has been found in humans.[30] Data also suggest that sevoflurane can safely be delivered at fresh gas flows as low as 1 L/min without significant production of a breakdown product named compound A (fluoromethyl-2,2-difluoro-1-[trifluoromethyl] vinyl ether), which is considered potentially nephrotoxic.[31]

Inhaled anesthetics cause a transient reversible depression in renal function. GFR, renal blood flow, urine output, and urinary excretion of sodium are decreased (Table 59.8). Probable mechanisms include loss of renal autoregulation, activation of neurohumoral factors (e.g., antidiuretic hormone, vasopressin, renin), and neuroendocrine responses. Although most inhaled anesthetics have been shown to reduce GFR and urinary excretion of sodium, studies examining their effects on renal blood flow have yielded conflicting results, which can be explained by differences in experimental methodology. Data suggest that renal blood flow is maintained with halothane, isoflurane, and desflurane[32,33] but that it is decreased with sevoflurane.[34]

Intravenous Anesthetics

Reversal of CNS effects after the administration of ultrashort-acting barbiturates such as thiopental and methohexital occurs as a result of redistribution, and hepatic metabolism is the sole route of elimination of these drugs. Thiopental is 75% to 85% bound to albumin,[35] the concentration of which may be markedly reduced in uremia.

TABLE 59.8 Effects of Various Anesthetics on Renal Function

	RBF	GFR	Urine Output	Urine Solutes
General anesthesia	↓	↓	↓	↓
Intravenous anesthetics				
Thiopental	↔	↓	↓	↓
Midazolam	↔	↔	↓	↔
Fentanyl (high dose)	↔	↔	↔	↔

Spinal epidural (without epinephrine)	↔↔	↔↔	↔↔	oo
Spinal	↔	↔	↔	o

GFR, Glomerular filtration rate; *PEEP*, positive end-expiratory pressure; *RBF*, renal blood flow; ↔, no significant change; *o,* significant data; ↓, decrease.

Although conflicting reports of anesthetic effects on RBF have been reported because of different investigative methods, the current literature seems to support these data.

From Hemmings HC Jr. Anesthetics, adjuvant drugs and the kidney. In: Malhotra V, ed. *Anesthesia for Renal and Genitourinary Surgery*, New York: McGraw-Hill: 1996;20.

Because it is a highly bound drug, reduced binding permits a greater proportion of an administered dose of thiopental to reach receptor sites. In addition, thiopental is a weak acid, with its pK_a in the physiologic range; acidosis results in more un-ionized, nonbound, active thiopental. In combination, these changes produce an increase in the free fraction of thiopental from 15% in normal patients to 28% in patients with CRF. With thiopental metabolism essentially unchanged in renal disease, the dose to produce and maintain anesthesia should be reduced.[36] The same considerations are true for methohexital, although metabolism plays a slightly greater part in the termination of its therapeutic effect.[37]

Propofol does not adversely affect renal function as reflected by measurements of creatinine concentration. Prolonged infusions of propofol may result in the excretion of green urine because of the presence of phenolic metabolites in the urine. This discoloration does not affect renal function. Urate excretion is increased after the administration of propofol and is usually manifested as cloudy urine when urate crystallizes under conditions of low pH and temperature.[38]

There are no reports of the disposition of narcotics and tranquilizers when used in large dosage for anesthesia in uremic patients. These drugs are extensively metabolized before excretion; therefore they should not have a particularly prolonged effect. The benzodiazepines, especially diazepam,[14] have a long half-life and tend to accumulate. Because of the greater ease of reversibility of the potent inhaled anesthetics versus intravenous drugs, inhaled anesthetics may offer some advantages for the induction of general anesthesia in uremic patients.

Muscle Relaxants and Their Antagonists

Succinylcholine has been used without difficulty in patients with decreased or absent renal function. Its metabolism is catalyzed by pseudocholinesterase to yield the nontoxic end products succinic acid and choline. The metabolic precursor of these two compounds, succinylmonocholine, is excreted by the kidneys. Large doses of succinylcholine, which might result from prolonged infusion, should be avoided in patients with renal failure. Although pseudocholinesterase levels are reduced in uremia,[39] these reductions are insufficient and cause a prolonged block. Hemodialysis has been reported to have no effect on cholinesterase levels.[40]

Administration of succinylcholine causes a rapid, transient increase of 0.5 mEq/L in the serum potassium concentration. In traumatized, burned, or neurologically injured patients, the increase may be 5 to 7 mEq/L, probably as a consequence of denervation supersensitivity of the muscle membrane to succinylcholine and to acetylcholine,[41] which can result in cardiovascular collapse. Likewise, an exaggerated increase in serum potassium could be particularly dangerous in uremic patients with hyperkalemia; therefore the use of succinylcholine is inadvisable, unless the patient has undergone dialysis within 24 hours before surgery. If the patient has recently undergone dialysis or has normal serum potassium, the use of succinylcholine is safe in the absence of other contraindications to the medication.

The disposition of nondepolarizing muscle relaxants has been well studied. Renal failure influences the pharmacology of nondepolarizing muscle relaxants by producing either decreased elimination of the drug or its metabolites by the kidney or decreased activity of enzymes that metabolize the drug, such as in the case of mivacurium (Table 59.9).

TABLE 59.9 Pharmacokinetics Data for Nondepolarizing Muscle Relaxants in Normal and Anephric Patients

Drug	Patients Studied	Elimination Half-Life (h)	Clearance (mL/kg/min)	Volume of Distribution (L/kg)
Vecuronium	Normal	0.9	5.3	0.20
	Anephric	1.4	3.1	0.24
Atracurium	Normal	0.3	6.1	0.18
	Anephric	0.4	6.7	0.22
Pancuronium	Normal	1.7	1	0.14
	Anephric	8.2	0.3	0.14
Rocuronium	Normal	0.71	2.9	0.207
	Anephric	0.97	2.9	0.264
Cisatracurium	Normal	—	5.2	0.031
	Anephric	—	—	—
Mivacurium	Normal	0.03	106	0.278
	Anephric	0.06	80	0.478

Consequently, the duration of action of muscle relaxants may be prolonged in patients with renal failure.

Approximately 40% to 50% of a long-acting nondepolarizing muscle relaxant, pancuronium, is excreted in urine. A portion of this excretion occurs after biotransformation to the less active metabolite 3-hydroxypancuronium.[42] Pancuronium has a prolonged terminal elimination half-life in patients with reduced renal function (see Table 59.9)[43]; therefore it should be administered cautiously, particularly when several doses are required.

Two nondepolarizing muscle relaxants, atracurium and vecuronium, were introduced into clinical practice during the early 1980s. Atracurium is degraded by enzymatic ester hydrolysis and nonenzymatic alkaline degradation (Hofmann elimination) to inactive products that are not dependent on renal excretion for termination of action.[44] Predictably, their terminal elimination half-life and indices of neuromuscular blockade (onset, duration, and recovery) are the same in patients with normal and absent renal function.[45]

Approximately 30% of a dose of vecuronium is eliminated by the kidneys. Lynam and colleagues[46] found that the duration of neuromuscular blockade after the administration of vecuronium was longer in patients with renal failure than in patients with normal renal function (99 vs. 54 minutes) because of a longer elimination half-life (83 vs. 52 minutes) and lower plasma clearance (3.1 mL/kg/min vs. 5.3 mL/kg/min). In a related area, an interaction between the solvent of cyclosporine (Kolliphor EL) with atracurium and vecuronium has been reported, with the action of these muscle relaxants potentiated in cats,[47] but it is unknown whether such potentiation also occurs in human renal transplant recipients.

Cisatracurium is the single cis isomer of atracurium. Organ-independent mechanisms (Hofmann elimination) account for 77% of the total clearance of cisatracurium. Because renal excretion accounts for only 16% of the elimination of cisatracurium, renal failure should have little effect on its duration of action.[45]

The short-acting drug mivacurium is metabolized by plasma pseudocholinesterase. Its effect has been shown to be lengthened by 10 to 15 minutes in patients with ESRD, most likely because of a decrease in plasma cholinesterase activity in these patients associated with uremia or hemodialysis[48,49] and there is a decrease in the mivacurium requirement by infusion in anephric patients.[49]

Rocuronium is an aminosteroid nondepolarizing muscle relaxant. The elimination half-life of rocuronium is increased in renal failure because of an increase in the volume of distribution with no change in clearance. This explanation might account for a longer duration of action in anephric patients, although its clinical significance is uncertain.[50]

Pharmacokinetics data for the cholinesterase inhibitors neostigmine, pyridostigmine, and edrophonium for normal, anephric, and renal transplant patients are presented in Table 59.10; there are no major differences among the three drugs.[51-53] Renal excretion is of major importance for the elimination of all three reversal drugs, with approximately 50% of neostigmine and 70% of pyridostigmine and edrophonium excreted in urine. Excretion of all the cholinesterase inhibitors is delayed in patients with impaired renal function to the same or perhaps to a slightly greater extent than is elimination of muscle relaxants. Reappearance of neuromuscular blockade after pharmacologic reversal of neuromuscular blockade in a patient with renal failure is, in most cases, due to some other cause. Table 59.10 contains data indicating that the pharmacokinetics of all the cholinesterase inhibitors is similar in healthy patients and in patients with well-functioning newly transplanted kidneys.

Sugammadex, a newer reversal drug, is a cyclodextrin molecule that inactivates aminosteroidal neuromuscular blockers, such as vecuronium and rocuronium, by selectively binding to them. The resultant sugammadex-neuromuscular blocker complex is excreted by the kidney. In patients with severe renal impairment, these cyclodextrin complexes can accumulate. Although sugammadex can effectively reverse neuromuscular blockade in these patients, the effect of prolonged exposure to sugammadex is unclear. There are insufficient data at this time to recommend the routine administration to patients with severe renal impairment.[54] There are also data to suggest that

TABLE 59.10 Pharmacokinetics Data for Cholinesterase Inhibitors in Normal, Anephric, and Renal Transplant Patients

Drug	Patients Studied	Elimination Half-Life (h)	Clearance (mL/kg/min)	Volume of Distribution (L/kg)
Neostigmine	Normal	1.3	8.4	0.7
	Anephric	3*	3.9*	0.8
	Renal transplant	1.7	9.4	1.1
Pyridostigmine	Normal	1.9	8.6	1.1
	Anephric	6.3*	2.1*	1
	Renal transplant	1.4	10.8	1
Edrophonium	Normal	1.9	8.2	0.9
	Anephric	3.6*	2.7*	0.7
	Renal transplant	1.4	9.9	0.9

*$P < .05$ vs. normal.

sugammadex complexes can be effectively dialyzed using high-flux hemodialysis.[55]

Vasopressors and Antihypertensive Drugs

Patients with severe renal disease are frequently given antihypertensive and other cardiovascular medications. More than 90% of the thiazides[56] and 70% of furosemide[57] are excreted by the kidneys, and they have prolonged durations of action in patients with abnormal or absent renal function. Propranolol is almost completely metabolized in the liver,[58] and esmolol is biodegraded by esterases in the cytosol of red blood cells[59]; therefore their effects are not prolonged in patients with abnormal or absent renal function. The calcium channel–blocking agents nifedipine, verapamil, and diltiazem are extensively metabolized in the liver to pharmacologically inert products; they can be administered in usual doses to patients with renal insufficiency.[60] Nitroglycerin can be useful because it is metabolized rapidly, with less than 1% excreted unchanged in urine.[61]

Sodium nitroprusside has had a resurgence in use since its initial introduction as a hypotensive drug in the 1920s. Cyanide is an intermediate in the metabolism of sodium nitroprusside, with thiocyanate being the final metabolic product. Although cyanide toxicity as a complication of sodium nitroprusside therapy is well described, it is less well appreciated that thiocyanate is also potentially toxic. The half-life of thiocyanate is normally more than 4 days, and it is prolonged in patients with renal failure. Hypoxia, nausea, tinnitus, muscle spasm, disorientation, and psychosis have been reported when thiocyanate levels are more than 10 mg/100 mL.[62] Sodium nitroprusside is less desirable for prolonged administration than either trimethaphan or nitroglycerin.

Hydralazine is slower acting than the other three drugs discussed previously. Its action is terminated by hydroxylation and subsequent glucuronidation in the liver, with approximately 15% excreted unchanged in urine.[63] The elimination half-life of hydralazine is prolonged in patients with uremia; therefore caution is required when it is administered.[64] After a single intravenous dose of 0.5 mg/kg of labetalol, the volume of distribution, clearance, and elimination half-life were similar in patients with ESRD and in healthy volunteers.[65]

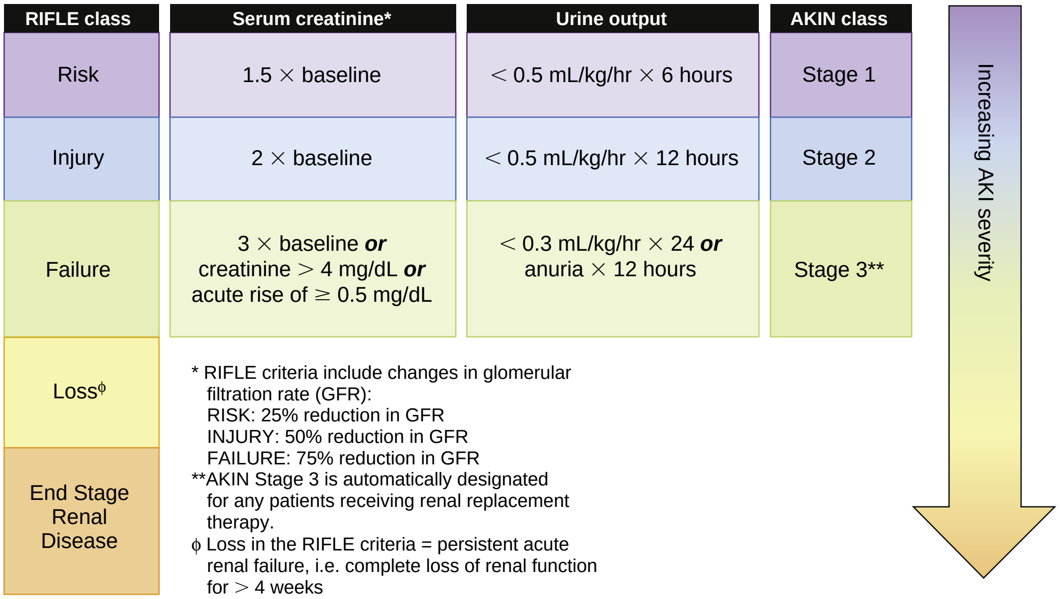
If administration of a vasopressor is necessary, a direct α-adrenergic–stimulating drug such as phenylephrine would be effective. This type of vasopressor causes the greatest interference with renal circulation. Although β-adrenergic–stimulating drugs such as isoproterenol maintain heart and brain perfusion without renal vasoconstriction, they also increase myocardial irritability. When possible, it is best to substitute simple measures such as blood volume expansion for drug therapy. If these measures are inadequate, β-adrenergic–stimulating drugs or dopamine should be used.

ACUTE KIDNEY INJURY AND HEMODIALYSIS

Although often considered a discrete syndrome, AKI represents a diverse array of pathophysiologic processes of varied severity and cause. These include decreases in GFR as the result of disruption of normal renal perfusion without causing parenchymal injury; partial or complete obstruction to urinary flow; and a spectrum of processes with characteristic patterns of glomerular, interstitial, tubular, or vascular parenchymal injury. AKI-precipitating events are quite often multifactorial and occur in a heterogeneous patient population.[66] Authors have used terms such as renal insufficiency, renal dysfunction, acute renal failure, and renal failure requiring dialysis somewhat interchangeably. Parameters used to define these terms include (Fig. 59.5) absolute and percentage changes in creatinine values, absolute and percentage changes in estimated GFRs, and reduction in output.[67] The incidence of AKI depends on the type of surgery and preexisting kidney function (Box 59.2 and Table 59.11).

In cardiac surgery, incidence is between 7.7% and 11.4%[68] when defined broadly, whereas frequency of AKI requiring dialysis is generally lower, ranging between less than 1% and 5%. In gastric bypass surgery, the incidence is 8.5%,[69] and after aortic aneurysm surgery, it is approximately 15% to 16%.[70] Similarly, liver transplant is also associated with a high frequency of AKI. It is reported that 48% to 94%[71] of patients suffer from acute worsening renal function after liver transplantation.

In noncardiac surgery, several independent risk factors for AKI have been identified by Kheterpal and coworkers[72]:



RIFLE class	Serum creatinine*	Urine output	AKIN class
Risk	1.5 × baseline	< 0.5 mL/kg/hr × 6 hours	Stage 1
Injury	2 × baseline	< 0.5 mL/kg/hr × 12 hours	Stage 2
Failure	3 × baseline ***or*** creatinine > 4 mg/dL ***or*** acute rise of ≥ 0.5 mg/dL	< 0.3 mL/kg/hr × 24 ***or*** anuria × 12 hours	Stage 3**
Loss$^{\phi}$			
End Stage Renal Disease			

Increasing AKI severity

* RIFLE criteria include changes in glomerular filtration rate (GFR):
RISK: 25% reduction in GFR
INJURY: 50% reduction in GFR
FAILURE: 75% reduction in GFR

**AKIN Stage 3 is automatically designated for any patients receiving renal replacement therapy.

ϕ Loss in the RIFLE criteria = persistent acute renal failure, i.e. complete loss of renal function for > 4 weeks

Fig. 59.5 Parameters used to define acute kidney injury *(AKI)*. (From Mehta RL, Kellum JA, Shah SV, et al. Acute Kidney Injury Network: report of an initiative to improve outcomes in kidney injury. *Crit Care*. 2007;11:R31.)

BOX 59.2 Risk Factors for Development of Postoperative Acute Kidney Injury

Preoperative Factors

- Preoperative renal dysfunction
- Increasing age
- Heart disease (ischemic or congestive)
- Smoking
- Diabetes mellitus
- American Society of Anesthesiologists Physical Status classification 4 or 5

Intraoperative Factors

- Emergency surgery or intraperitoneal, intrathoracic, suprainguinal vascular surgeries
- Erythrocyte transfusion
- Inotrope use
- Aortic cross-clamp time
- Cardiopulmonary bypass: furosemide use, urine output, need for a new pump run

Postoperative Factors

- Erythrocyte transfusion
- Vasoconstrictor use
- Diuretic use
- Antiarrhythmic drug use

Data from Abelha FJ, Botelho M, Fernandes V, et al. Determinants of postoperative acute kidney injury. *Crit Care*. 2009;13:R19; Parolari A, Pesce LL, Pacini D, et al. Risk factors for perioperative acute kidney injury after adult cardiac surgery: role of perioperative management. *Ann Thorac Surg*. 2012;93:584–591.

age, emergent surgery, liver disease, body mass index, high-risk surgery, peripheral vascular disease, and chronic obstructive pulmonary disease (requiring chronic bronchodilator therapy). Based on incremental score, the frequency of renal failure increased, ranging between 0.3% and 4.5%, respectively.

PERIOPERATIVE MANAGEMENT OF PATIENTS WITH ACUTE KIDNEY INJURY

Although many factors have been shown to contribute to AKI in surgical patients, there are few interventions to prevent AKI and no obvious cure for perioperative renal injury. A complete review of such interventions is beyond the scope of this chapter; however, some deserve mention.

Dialysis

Dialysis may not decrease perioperative AKI; however, it can treat the associated acidosis, hyperkalemia, and hypervolemia. For certain surgeries, such as aortic, dialysis actually reduces 30-day mortality rates in patients who develop loss of renal function. As many as 75% of these survivors regain kidney function and become independent of dialysis.[73]

Nondialytic Management

Optimal therapy for renal dysfunction has not been established, and it is not clear whether interventions such as ACE-I therapy or diuretic therapy prevent decline in kidney function around the time of surgery.[68]

Normal hemodynamic variables probably should be preserved during the operative period in an attempt to prevent AKI. In addition, scavengers of oxygen free radicals such as mannitol and *N*-acetylcysteine have been given to prevent ischemia-reperfusion injury. However, studies implementing these strategies have failed to show benefit in reduction of AKI in cardiac surgery patients. For years, mannitol was administered before aortic clamping, especially prior to the application of a suprarenal cross-clamp during abdominal aortic aneurysm. Clinical trials thus far have failed to demonstrate that this approach reduces the incidence of renal failure in this population of patients.[74]

Both dopamine and atrial natriuretic peptide initially showed promise in the prevention of AKI because of their vasoactive effects leading to increased renal blood flow.

TABLE 59.11 Common Causes of Postoperative Decreased Urine Output and Acute Kidney Injury

	SITE OF DEFECT		
	Prerenal	**Renal**	**Postrenal**
Differential Diagnoses	Hypotension Absolute Relative	Acute tubular necrosis Ischemia-reperfusion Radiocontrast	Urinary catheter obstruction Catheter kinking Debris
	Hypovolemia	Acute interstitial nephritis	Prostatic hypertrophy
	Absolute Relative (e.g., IAH)		Bladder spasm Urinary retention

From Chenitz KB, Lane-Fall MB. Postoperative oliguria. *Anesth Clin*. 2012;513–526.

Studies have shown neither dopamine[75] nor atrial natriuretic peptide[76] to be associated with improved mortality. Use of fenoldopam, a selective renal dopamine receptor agonist, has been shown to reduce postoperative AKI; however, it has not been associated with a reduction in the need for renal replacement therapy or hospital mortality.[77]

Renal and Genitourinary Procedures

TRANSURETHRAL RESECTION OF THE PROSTATE

Transurethral resection of the prostate (TURP) is associated with a particular set of concerns with anesthetic implications. These issues must be considered when choosing an anesthetic technique, along with the usual considerations, such as the general health of the patient, the length of the procedure, and patient and surgeon preferences.

Pathophysiology of Prostate Hyperplasia

The prostatic gland is often described as a walnut-sized organ at the base of the bladder. There are three major areas—the fibromuscular stroma that surrounds the gland and two glandular zones termed central and peripheral. There is also a smaller, approximately 5% of the normal prostate, glandular region that surrounds the prostatic urethra designated as the transition zone; which is the primary site of benign prostatic hyperplasia (BPH). Nodular expansion of this area causes compression of the urethra along with the associated partial bladder outlet obstruction in men.[78] The prostate is rich in blood supply with vessels penetrating the prostatic capsule and branching within the gland. There are also large venous sinuses adjacent to the capsule.[79] The prevalence of BPH increases precipitously from the fourth decade of life, peaking at 88% of men in their 80s.[80]

Surgical Procedures

TURP has long been considered the “gold standard” for the surgical treatment of BPH. Over the past several decades, the number of monopolar TURP (M-TURP) procedures performed annually in the United States has steadily declined secondary to advances in medical management, α-blockers, and 5-α reductase inhibitors; the introduction of newer surgical treatment modalities, bipolar TURP (B-TURP), laser TURP (L-TURP), microwave ablation, and aquablation; and the development of patient care guidelines.[81-84]

The TURP procedure is performed by inserting a resectoscope through the urethra and resecting or vaporizing prostatic tissue in an orderly fashion. This can be accomplished using one of several techniques: M-TURP or B-TURP using an electrically powered cutting-coagulating metal loop, Holmium laser enucleation of the prostate (HoLEP), bipolar plasma vaporization, or laser-vaporization.[82,85-87] A recently introduced novel technique is aquablation, a minimally invasive water ablation technique combining image guidance and robotics with a high-velocity saline stream for targeted and heat-free removal of prostatic tissue.[83] During resection, care must be taken not to violate the prostatic capsule. If the capsule is violated, large amounts of irrigation fluid may be absorbed into the circulation via the periprostatic or retroperitoneal spaces. If perforation is suspected, the procedure should be quickly terminated and hemostasis should be established.[88]

Bleeding during M-TURP is common but is usually easily controlled. Arterial bleeding is controlled by electrocoagulation; however, when large venous sinuses are opened, hemostasis becomes difficult. If bleeding becomes uncontrollable, the procedure should be terminated as quickly as possible, and a Foley catheter should be passed into the bladder and traction applied. Excessive bleeding requiring transfusion occurs in approximately 2.5% of M-TURP procedures.[89]

Irrigation Solutions

Ideally, an irrigation solution for use during TURP should be isotonic, nonhemolytic, electrically inert, transparent, nonmetabolized, nontoxic, rapidly excreted, easily sterilized, and inexpensive.[90,91] Such a solution does not exist. Initially, the solution of choice for M-TURP was distilled water because it is electrically inert, transparent, and inexpensive, but it is extremely hypotonic. When absorbed into the circulation, it causes massive hemolysis, hyponatremia, renal failure, and CNS symptoms.[92] Solutions of normal saline or Ringer lactate are isosmotic and are tolerated if absorbed into the circulation but are highly ionized and would cause dispersion of the high-frequency current from the M-TURP resecting loop. These issues led to the use of nearly isotonic irrigation solutions, such as glycine, Cytal (a combination of 2.7% sorbitol and 0.54% mannitol), sorbital, mannitol, glucose, and urea (Table 59.12). These solutions allow for electrocautery and are moderately hypotonic to maintain transparency.[93,94]

Although these irrigation solutions cause no significant hemolysis, excessive absorption can lead to several

TABLE 59.12 Osmolality of Irrigation Solutions Used for Transurethral Resection of the Prostate

Solution	Osmolality (mOsm/kg)
Glycine, 1.2%	175
Glycine, 1.5%	220
Cytal (see text)	178
Sorbital, 3.5%	165
Mannitol, 5%	275
Glucose, 2.5%	139
Urea, 1%	167
Distilled water	0

perioperative complications, such as circulatory overload, pulmonary edema, and hyponatremia. In addition, the solutes can have adverse effects: glycine can cause cardiac, neurologic, and retinal effects; mannitol rapidly expands the blood volume and can cause pulmonary edema in cardiac compromised patients; sorbital is metabolized to fructose and lactate, and may cause hyperglycemia and/or lactic acidosis; and glucose can cause severe hyperglycemia in diabetic patients.

Replacement of distilled water with nearly isosmotic solutions has eliminated hemolysis and its sequelae as a complication of M-TURP. The incidence of severe CNS symptoms associated with severe hyponatremia, such as seizures and coma, has been reduced. However, the other major complication associated with the absorption of large volumes of irrigation solutions, overhydration, still is present. The use of normal saline as the bladder irrigation solution with the newer surgical techniques has eliminated the risks of dilutional hyponatremia and TURP syndrome.

Anesthetic Considerations for Transurethral Resection of the Prostate

Spinal anesthesia is considered the anesthetic technique of choice when traditional M-TURP is performed.[95] Spinal anesthesia provides adequate anesthesia for the patient with relaxation of the pelvic floor and perineum for the surgeon. Cardiac morbidity and mortality after M-TURP were similar for general or regional[96]; however, spinal anesthesia has the advantage of allowing the patient to remain awake and enables the anesthesiologist to recognize the early signs and symptoms (e.g., mental status changes) of TURP syndrome or the extravasation of irrigating solution. Restlessness and confusion are early signs of hyponatremia and/or serum hypoosmolality and generally not signs of inadequate anesthesia. The continued administration of sedatives or the induction of general anesthesia might mask severe complications of TURP syndrome and even lead to death.[97]

A sensory level of T10 provides satisfactory regional anesthesia for TURP by achieving an anesthetic block level that interrupts sensory transmission from the prostate and bladder neck; in addition, this sensory level eliminates the uncomfortable sensation of bladder distention. Higher sensory levels might mask the symptoms (abdominal or shoulder pain and/or nausea and vomiting) of accidental perforation of the bladder or prostatic capsule in the awake patient.[94]

Spinal anesthesia has a few advantages over epidural anesthesia for TURP. It is considered to be technically easier to perform in elderly patients. The incomplete block of the sacral nerves, which provide sensory innervation to the prostate, bladder neck, and penis, occasionally occurs with epidural anesthesia and is usually avoided with spinal anesthesia. However, if a regional technique cannot be performed because of technical difficulty, concerns of sacral nerve coverage, coagulation status, and/or patient refusal, then general anesthesia will be required.

Controversy exists on whether regional or general anesthetic techniques influence blood loss during TURP. Some studies have reported decreased bleeding under regional anesthesia,[98-100] whereas others found no significant difference between the techniques.[101-104] Taking into consideration the studies that observed decreased bleeding with regional anesthesia, the authors have postulated that regional anesthesia reduces blood loss not only by decreasing systemic blood loss but also by decreasing central and peripheral venous pressures. However, spinal anesthesia, by reducing central venous pressure (CVP), may allow for greater absorption of irrigating solution compared to general anesthesia.[105] Additional factors that influence blood loss during TURP are the vascularity and size of the gland, the duration of the procedure, the number of sinuses opened during resection, and the presence of infection and prostatic inflammation from repeated or recent catheterizations.[89,95]

Anesthetic considerations for TURP should also include positioning. TURP is usually performed in the lithotomy position with a slight Trendelenburg tilt. This positioning results in changes in pulmonary blood volume; a decrease in pulmonary compliance; a cephalad shift of the diaphragm; and a decrease in lung volumes such as residual volume, functional residual volume, tidal volume, and vital capacity. Cardiac preload may also increase. Nerve injuries to the common peroneal, sciatic, and femoral nerves may occur.[106]

Morbidity and Mortality After Transurethral Resection of the Prostate

Patients presenting for TURP are often elderly and tend to have coexisting diseases. With a reported 30-day mortality rate associated with M-TURP to be between 0.2% and 0.8%, the common causes of death include pulmonary edema, renal failure, and myocardial infarction.[95,107] Mortality rates are similar in patients receiving regional anesthesia or general anesthesia.[108] In one study the postoperative morbidity rate was noted to be 18%, with increased postoperative morbidity seen in patients with acute urinary retention, gland size greater than 45 g, resection exceeding 90 minutes, and age older than 80 years.[95]

The most concerning complication of M-TURP is TURP syndrome. This syndrome has a multifactorial pathophysiologic presentation and is essentially an iatrogenic form of water intoxication caused by a combination of excessive absorption of irrigating solution and the resulting hyponatremia.[109] Large studies have reported an incidence rate of mild to moderate TURP syndrome of between 0.78% and 1.4%.[110,111] However, a mortality rate as high as 25% has been reported for severe TURP syndrome (serum sodium concentration <120 mEq/L).[112]

Another concern, because many of the patients for TURP are elderly, is the incidence of postoperative cognitive dysfunction. In a small prospective study comparing spinal anesthesia with intravenous sedation to general anesthesia in elderly TURP patients, significant reduction in cognitive function was noted in both groups after 6 hours, with no difference in perioperative mental function between the groups at any time or even after 30 days.[113]

COMPLICATIONS OF TRANSURETHRAL RESECTION OF THE PROSTATE

Absorption of Irrigating Solution

In almost every TURP procedure, irrigating solution is absorbed through opened prostatic venous sinuses. Several factors govern the amount and rate of absorption: (1) the height of the irrigating solution above the surgical table, which affects hydrostatic pressure; (2) the amount of distension of the bladder; (3) the extent of opened venous sinuses; and (4) the length of surgical resection time.[114] On average, 10 to 30 mL of fluid is absorbed per minute of resection time, with the possibility of 6 to 8 L absorbed in procedures lasting up to 2 hours. Whether patients experience complications as a consequence of absorption of irrigating solution depends on the amount and type of fluid absorbed.[115,116]

Excessive Circulatory Volume, Hyponatremia, and Hypoosmolarity

The rapid volume expansion that occurs with excessive absorption of irrigation fluid leads to circulatory overload. Initially, hypertension and bradycardia may be observed, and in patients with compromised cardiac function, this could progress to pulmonary edema and eventually cardiac arrest.[117] After the initial hypertensive stage, a period of prolonged hypotension may follow. One suggested mechanism is the combination of hypertension and hyponatremia, which causes a net water flux along osmotic and hydrostatic pressure gradients out of the intravascular space into the pulmonary interstitium, causing pulmonary edema and hypovolemic shock.[118-120] In addition, the release of endotoxins into the circulation with the associated metabolic acidosis also causes hypotension.[121,122] Whether symptoms of circulatory overload occur in a given patient depends on the patient's cardiovascular status, the amount and rapidity of absorption of irrigating fluid, and the extent of surgical blood loss.[116]

The severity of symptoms of hyponatremia correlate with the rate by which serum sodium concentration falls. Acute changes in serum sodium levels are more concerning than chronic hyponatremia.[123] In addition, it is often impossible to separate symptoms of cardiovascular compromise caused by hyponatremia from those secondary to circulatory overload. CNS symptoms and cardiovascular effects are observed with acute decreases in serum sodium levels to less than 120 mEq/L. At first, one may observe restlessness and confusion, and with continuing decreases in serum sodium levels this may progress to loss of consciousness and seizures (<110 mEq/L). Hypotension, pulmonary edema, and congestive heart failure may also occur at serum sodium levels of less than 120 mEq/L, along with electrocardiogram changes (widened QRS complexes, ventricular ectopy, and ST segment increases) observed at levels less than 115 mEq/L. Eventually at levels near 100 mEq/L, respiratory and cardiac arrest may occur.[124]

The classic CNS signs of TURP syndrome are thought to be not caused by hyponatremia itself but are due to the acute serum hypoosmolality that allows the shift of intravascular fluid into the brain and consequent cerebral edema. With the advent of modern nonelectrolyte irrigating solutions, the incidence of severe CNS complications has been reduced; however, CNS disturbances can still occur secondary to severe hyponatremia.[115,116]

Glycine Toxicity

Glycine is a nonessential amino acid and when absorbed in significant amounts may cause neurologic and cardiac effects. Glycine has been implicated as the probable cause of transient blindness in TURP patients. Centrally acting mechanisms, such as cerebral edema, may also cause visual impairment, but normal pupillary light reflexes are retained. In TURP patients with transient blindness, the pupils are sluggish or nonreactive, suggesting a retinal effect. Glycine is an inhibitory neurotransmitter of the retina, and in one investigation, prolongation of visual evoked potentials along with deterioration of vision was observed after absorption of a few hundred milliliters of 1.5% glycine irrigation.[125] Glycine has also been shown to have subacute effects on the myocardium with the appearance of T-wave depressions or inversions on electrocardiography; and CK-MB isoenzymes may be elevated in some patients, without meeting criteria for myocardial infarction, for up 24 hours after surgery.[126]

Ammonia Toxicity

Because glycine is metabolized in the liver into ammonia, absorption of glycine may result in CNS toxicity.[127] The early signs of ammonia toxicity, nausea and vomiting, usually occur within 1 hour after surgery. CNS signs and symptoms are observed when serum concentrations of ammonia are greater than 100 μmol/L.[128] With higher levels, patients may lapse into a coma lasting from 10 to 12 hours and awaken after levels decrease to less than 150 μmol/L.[94]

Bladder Perforation

Inadvertent perforation of the bladder during TURP is another common complication, with a reported incidence of approximately 1% and with most perforations occurring retroperitoneally.[129] The usual cause is surgical instrumentation or overextension of the bladder with irrigating solution. An early sign of perforation, often overlooked, is a decrease in the return of irrigating solution. Eventually, a significant volume of fluid accumulates in the abdomen causing distension; conscious patients with a regional anesthetic may complain of abdominal pain and/or experience nausea and vomiting. With intraperitoneal perforations, symptoms are similar and develop sooner, and a patient may complain of severe shoulder pain secondary to diaphragmatic irritation. Intraperitoneal perforations are treated with either open surgical repair or percutaneous drainage of the abdomen.[130]

Transient Bacteremia and Septicemia

The prostate harbors a variety of bacteria, which can be a source of perioperative bacteremia via opened prostatic venous

TABLE 59.13 Signs and Symptoms of Transurethral Resection of the Prostate Syndrome

Cardiovascular and Respiratory	Central Nervous System	Metabolic	Other
Hypertension	Agitation/confusion	Hyponatremia	Hypoosmolality
Bradyarrhythmias, tachyarrhythmias	Seizures	Hyperglycinemia	Hemolysis
Congestive heart failure	Coma	Hyperammonemia	Acute renal failure
Pulmonary edema and hypoxemia	Visual disturbances (blindness)		
Myocardial infarction			
Hypotension			

sinuses. The presence of an indwelling catheter will further increase this risk. Therefore the prophylactic administration of antibiotics in patients is recommended for TURP procedures. The bacteremia is usually transient, symptomless, and easily treated with common antibiotic combinations; however, 6% to 7% of these patients may develop septicemia.[95]

Hypothermia

Using room temperature irrigating solutions may cause shivering and hypothermia in patients undergoing TURP procedures. This may be especially noticeable in older populations who have a reduced thermoregulatory capacity.[131] Warming the irrigation solutions will decrease heat loss and shivering. Concerns that these warmed solutions may cause increased bleeding secondary to vasodilation has not been shown to be clinically significant.[132,133]

Bleeding and Coagulopathy

Estimates of blood loss during TURP are frequently inaccurate secondary to the mixing of blood with large volumes of irrigating solution. Blood loss during M-TURP has been estimated to range from 2 to 4 mL/min of resection time or 20 to 50 mL/g of resected prostatic tissue[89]; however, these guidelines are rough estimates, and the careful monitoring of the patient's vital signs and serial hematocrits should be used to assess blood loss and the need for transfusion.

Abnormal bleeding after TURP occurs in less than 1% of cases. Possible causes include dilution of platelets (dilutional thrombocytopenia) and coagulation factors secondary to the absorption of large volumes of irrigating solutions, as well as systemic coagulopathy. In these patients, systemic coagulopathy is caused by either primary fibrinolysis or disseminated intravascular coagulopathy. In primary fibrinolysis, the prostate releases a plasminogen activator that converts plasminogen into plasmin, which then increases bleeding via fibrinolysis. If primary fibrinolysis is suspected, treatment is with epsilon aminocaproic acid given intravenously in a dose of 4 to 5 g during the first hour, followed by an infusion of 1 g/h. Some clinicians believe that the systemic absorption of resected prostatic tissue, which is rich in thromboplastin, will trigger the onset of disseminated intravascular coagulopathy.[89] Treatment is supportive with administration of intravenous fluid and blood products as required.

Treatment of Transurethral Resection of Prostate Syndrome

TURP syndrome may occur as early as a few minutes after the start of the procedure and as late as several hours after completion. A high index of awareness of the signs and symptoms (Table 59.13) must be present among the surgical team. Initially, based on the patient's symptomatology, supplemental oxygenation, ventilation, and cardiovascular support should be provided; concomitantly, other treatable conditions such as hypercarbia, hypoglycemia and diabetic coma, or drug interactions should be considered.[90] If TURP syndrome is suspected, blood samples should be drawn for analysis of electrolytes, glucose, and arterial blood gases and a 12-lead electrocardiogram should be obtained. Furthermore, the surgeon should terminate the procedure as rapidly as possible.[94]

Treatment of hyponatremia and volume overload is guided by the severity of the patient's symptoms. If the serum sodium level is greater than 120 mEq/L and the patient's symptoms are mild, then fluid restriction and the administration of a loop diuretic, usually furosemide, will usually return the serum sodium to normal levels.

In severe cases of TURP syndrome accompanied by a serum sodium less than 120 mEq/L, treatment with intravenous hypertonic saline (3% sodium chloride) should be considered. Cerebral edema and central pontine myelinolysis have been associated with rapid correction of hyponatremia with hypertonic saline.[134,135]

Laser Resection, Plasma Vaporization, Microwave Ablation, and Aquablation of the Prostate

In an effort to reduce perioperative morbidity, the urologic community has developed surgical alternatives to the classic TURP and M-TURP. The main advantage of these newer technologies is the use of physiologic saline instead of hypoosmolar irrigating solutions, such as glycine, which avoids the potential of dilutional hyponatremia and the development of TURP syndrome.[136] However, the possibility of volume overload is still present. Other advantages observed with these recent surgical modalities are a reduction of intraoperative and postoperative bleeding, less absorption of irrigation fluid, and decreased hospital length of stay. Although spinal anesthesia is the preferred anesthetic for TURP and M-TURP because it allows one to monitor mental status, these newer techniques enable the anesthesiologist to tailor the anesthetic management based upon the patient's medical condition and preference. In addition, patients may be taking anticoagulation medications or have coagulation disorders that may preclude the use of spinal anesthesia or undergoing the classic or M-TURP procedure.[137-139]

Laser resection of the prostate (L-TURP) has become an increasingly common choice for the treatment of BPH. L-TURP delivers light energy that, depending upon the temperature the prostatic tissue is heated to, will determine whether the tissue is coagulated or vaporized.[82] HoLEP has been suggested as the new gold standard for surgical treatment of BPH.[85,140]

Holmium:yttrium-aluminum-garnet laser is a solid-state, high-powered, pulsed laser that emits light at a wavelength of 2140 nm with precise cutting capabilities. Prostatic tissue is vaporized, and the resulting heat dissipation coagulates small to medium blood vessels. This technique allows the retrograde resection of entire prostatic lobes from the capsule, which are then pushed into the bladder and removed with a soft-tissue morcellator. HoLEP can be used safely on patients with larger prostatic glands, greater than 70 to 100 g, with similar outcomes as patients undergoing open prostatectomy.[141] When compared with traditional M-TURP, HoLEP is associated with lower transfusion rates, catheterization time, and shorter hospital stays.[142-145]

Another advancement in laser therapy for BPH is the development of the photoselective vaporization of prostate (PVP) technique. The initial 80-watt KTP (potassium-titanyl-phosphate) laser is a high-powered neodymium:yttrium-aluminum-garnet laser that passes a beam through a KTP crystal, which halves the wavelength to 532 nm and doubles the frequency of light. The 532-nm wavelength is selectively absorbed by hemoglobin and blood-rich tissue, poorly absorbed by water, and vaporizes prostatic tissue with minimal dissipation of energy to surrounding tissues. Higher-powered, 120- and 180-watt systems have been introduced that use a lithium triborate crystal that allow for faster vaporization and coagulation of prostatic tissue.[82,146]

This yields an almost bloodless field, faster hemostatic closure of the venous sinuses, and reduced absorption of irrigation fluid. Several studies have shown that PVP is safe and effective in patients at high risk of discontinuing their anticoagulation therapy for the procedure.[147-149] Potential complications of PVP include capsular perforation, dysuria, and infection (secondary to necrotic tissue that occurs with coagulation). When compared with M-TURP, reoperation rates were higher for PVP for residual adenoma but decreased with the 180-watt powered systems.[82] This laser modality allows the anesthesiologist to choose an anesthetic technique, including intravenous sedation, based on the patient's medical condition and preference.[150]

A recent nonlaser advance in the surgical treatment of BPH is the bipolar plasma vaporization of prostate technique. The design of this bipolar system incorporates both the active and return poles on the same electrode; as a consequence, in contrast to a monopolar system, energy does not transverse the patient's body toward a return electrode pad, but instead it remains at the site of prostate vaporization. The plasma vaporization system produces a plasma corona on the surface of a spherical shaped (described as mushroom- or button-like) tipped bipolar electrode. This electrode generates a thin layer of highly ionized particles as it glides over the prostatic tissue without making direct tissue contact, produces minimal heat, and concomitantly vaporizes and coagulates the tissue. The plasma field vaporizes a limited layer of prostate cells with significantly reduced bleeding.[87]

Transurethral microwave thermotherapy (TUMT) of the prostate is considered an effective alternative to M-TURP that has fewer major complications and can be performed as a minimally invasive office-based procedure under local or sacral block. TUMT heats prostatic tissue via a specialized catheter to a temperature between 45°C and 65°C. Although TUMT is less effective than M-TURP in reducing urinary flow long term, it is an alternative consideration for elderly or high-risk patients.[86,151]

The newest modality to surgically treat BPH is aquablation, a minimally invasive high-velocity saline ablation technique combining ultrasonic image guidance and robotics for the targeted and heat-free removal of prostatic tissue under general anesthesia. Using the ultrasonic image, the area of the prostate to be resected is mapped and the system generates and adjusts the level of saline pressure for the controlled ablation of the prostate tissue. Directed cautery of the resected area for hemostasis is then performed using either monopolar or bipolar techniques. In initial small studies of this technique, perioperative changes in serum sodium or hematocrit were not significant. Because the resection time is approximately 5 minutes and overall procedure time is 45 minutes, compared with other techniques with longer operative times, this technique may have an improved safety profile. Surgical mapping enables preservation of the bladder neck and tissue surrounding the verumontanum and therefore preservation of normal sexual function. Further clinical studies are needed to validate this new technology.[83,152]

URETEROSCOPIC LITHOTRIPSY AND PERCUTANEOUS NEPHROLITHOTRIPSY

Nephrolithiasis is a common and costly disease with a reported prevalence of 8.8% in the United States.[153] Although the majority of patients with renal system stones are conservatively managed, those with more complex calculi will require surgical treatment. The most commonly used surgical modalities are ureteroscopy (URS) and percutaneous nephrolithotomy (PCNL). The choice of treatment is guided by the size and location of the stone within the renal system. URS is recommended in symptomatic patients with smaller non–lower pole renal stones and/or middle or distal ureteral calculi. It has a greater stone-free rate after a single procedure when compared with extracorporeal shock wave lithotripsy (ESWL). In symptomatic (flank pain) patients with a renal stone burden greater than 20 mm or with lower renal pole calculi greater than 10 mm, PCNL should be the treatment of choice. PCNL with higher stone burdens and lower renal pole stones has a higher stone-free rate but carries greater morbidity.[154]

The advent of small-diameter, flexible ureteroscopes and the miniaturization of electrohydraulic lithotripsy (EHL) probes, especially laser fibers, have changed the anesthetic concerns associated with this procedure. Initially, URS was performed with larger, rigid instruments requiring ureteral dilation necessitating the patient to undergo a general or regional anesthetic for these procedures. The presumed advantage of these techniques is that they would prevent patient movement, therefore decreasing the risk of ureteral trauma. Although the use of a general or regional anesthetic is still common, studies have shown that URS can be safely and efficiently performed under local or intravenous sedation.[155-157]

EHL uses a flexible probe inserted through the ureteroscope to deliver a high-voltage spark between two electrodes generating a spherical hydraulic shock wave and the formation of a cavitation bubble near the stone to be fragmented. EHL can be performed in a normal saline solution, therefore avoiding the risks of irrigating the urinary track with a hypotonic solution. The major concern of EHL is its ability to damage the ureteral mucosa that could lead to the possibility of ureteral perforation. Laser lithotripsy uses a holmium:YAG flexible laser fiber through the ureteroscope to vaporize the stone via a photothermal mechanism. The holmium laser technique is safer and more efficient than EHL because it can be used in closer proximity to the ureteral wall without causing mucosal harm. In addition, it produces significantly smaller stone fragments.[155]

PCNL is the preferred modality for the treatment of large (>20 mm) or complex stones. Contraindications to PCNL include patients with uncorrected coagulopathy and active, untreated urinary tract infections. With the fragmentation of stones, bacteria and bacterial endotoxins may be released, which place the patient at risk for septic complications. To reduce this risk, broad-spectrum antibiotics should be given perioperatively to these patients. Renal access is obtained under fluoroscopic or ultrasonic guidance with the placement of a sheath through which a rigid or flexible nephroscope is inserted. Stone removal then may be achieved by a variety of endoscopic techniques. Commonly PCNL is performed in the prone position under general anesthesia, although regional anesthesia and local anesthesia with sedation have been successfully used.[155] Supine positioning may be used, but results in a smaller surgical field, collapse of the renal collecting system, and increased difficulty in upper pole calyceal puncture.[158] Besides the typical anesthetic concerns, including those related to prone positioning, PCNL has certain additional risks. Pleural injuries, including pneumothorax and hydrothorax; hypothermia secondary to the large amounts of fluid administered to the patient during nephroscopy; and acute anemia from bleeding or dilution may occur. Careful monitoring of the patient's pulmonary status (airway pressures, end-tidal CO_2, and O_2 saturation), hemodynamics, and temperature may alert one to these potential complications.[155]

EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY

ESWL is an alternative treatment for the disintegration of renal stones in the non–lower pole of the kidney and the upper part of the ureter. Although ESWL was considered the treatment of choice for these types of stones, it has been surpassed in the United States by URS.[159] In symptomatic patients with stone burdens smaller than 20 mm, ESWL is still an effective treatment; however, when compared with URS, it is associated with a higher likelihood of repeat procedures. Therefore, to optimize stone-free rates, successful treatment with ESWL depends upon several factors: obesity, skin-to-stone distance, collecting system anatomy, stone composition, and stone density/attenuation.[154] The original first-generation lithotripter (Dornier HM-3) required immersion of the patient into a water bath, which could result in significant effects in the cardiovascular and respiratory systems (Box 59.3). Newer generations of lithotripters use less power and have eliminated the water bath; therefore the efficiency of stone fragmentation is decreased, resulting in higher retreatment rates.[160]

BOX 59.3 Changes on Immersion During Lithotripsy

Cardiovascular	Increased	Central blood volume
	Increased	Central venous pressure
	Increased	Pulmonary artery pressure
Respiratory	Increased	Pulmonary blood flow
	Decreased	Vital capacity
	Decreased	Functional residual capacity
	Decreased	Tidal volume
	Increased	Respiratory rate

Lithotripters generate repetitive high-energy shock waves through the water density of the patient's tissues, which are focused on the stone, causing it to fragment. The original first-generation lithotripter utilized an electrohydraulic shock wave generated by an electrode (or spark plug) placed in a water bath. This spark caused an explosive vaporization of water resulting in the rapid expansion and collapse of gas bubbles that generate a pressure wave, which is then focused using a metal ellipsoid onto the stone. Newer generations use piezoelectric crystals or electromagnetic generators to produce these shock waves along with water-filled cones or cushions, or silicone membranes and/or gel, for air-free coupling of the generated shock wave to the patient.[161]

Biomechanical Effects of Shock Wave Therapy

For ESWL shock waves to be effective, there should be no movement of stones during treatment. Otherwise treatment time will be prolonged, while shock wave generation is suspended, until the stone returns or is retargeted to the treatment focal zone; or if shocks are continued, adjoining tissues may become injured from the energy of the shock waves. Using controlled ventilation during a general anesthetic may cause stone excursion to surpass 60 mm. Spontaneous ventilation has been observed to displace stones over 12 mm, whereas in patients with adequate sedation, stone excursion is limited to approximately 5 mm.[161]

For effective stone disintegration, shock waves should reach the stone unimpeded. The flank area should be kept free of any medium that would provide an interface for the dissipation of shock wave energy. Nephrostomy dressings should be removed, and the nephrostomy catheter should be taped clear of the blast path. Although shock waves pass through most tissues relatively unimpeded, they do cause tissue injury, the extent of which depends on the tissue exposed and the shock wave energy at the tissue level. Skin bruising and flank ecchymoses can occur at the entry site. Painful hematoma in the flank muscles may also occur. Hematuria is almost always present at the end of the procedure and results from shock wave–induced endothelial injury to the kidney and ureter. Adequate hydration is necessary to prevent clot retention.

Shock wave–induced cardiac dysrhythmias were previously reported in 10% to 14% of patients undergoing immersion lithotripsy.[163,164] Depending on the technology of the newer generations of lithotripters, some authors have observed dysrhythmias in 20% to 59% of patients with piezoelectric source of shock waves versus 1.4% to 9% using electromagnetic lithotripters. These dysrhythmic episodes do not seem to be of any clinical significance.[162] Some of these dysrhythmias may be due to mechanical stress on the conduction system exerted by the shock waves. The intricate grounding system of the lithotripter ensures that any current-induced dysrhythmias are unlikely. Artifacts on the electrocardiogram also are common. Artifacts and dysrhythmias usually disappear when the lithotripsy is stopped.

Anesthetic Choices for Lithotripsy

Historically, anesthetic regimens used successfully for immersion lithotripsy included general anesthesia, epidural anesthesia, spinal anesthesia, flank infiltration with or without intercostal blocks, and analgesia-sedation, including patient-controlled analgesia.[165-172] With the newer generations of lithotripters, most analgesia-sedation combinations are adequate. Even patient-controlled analgesia with alfentanil and a combination of propofol and alfentanil has been used.[173,174] Many centers routinely use general anesthesia with short-acting inhaled or intravenous anesthetics and use laryngeal mask airway for ventilation.

Newer Generations of Lithotripters

Newer generations of lithotripters have no water bath, use fluoroscopy and/or ultrasonography to visualize and target the stone, and tend to use multifunctional tables that allow other procedures, such as cystoscopy and stent placement, to be accomplished without moving the patient off the table. The shock waves are tightly focused; therefore, they cause less pain at the entry site, and intravenous analgesia-sedation is the mainstay of anesthesia with these newer lithotripters. Other incidental interventions, such as cystoscopy, stone manipulation, or stent placement, may alter anesthetic requirements. Because these newer lithotripters have a much smaller focal zone for the shock waves, it is essential that adequate analgesia and sedation be provided so that stone excursion with respiration is limited to the focal zone.

Contraindications

Pregnancy, active urinary tract infection, and untreated bleeding disorders are the major contraindications to lithotripsy. Women of childbearing age must have a pregnancy test that is documented to be negative before lithotripsy. Standard tests of coagulation, such as the platelet count, prothrombin time, and partial thromboplastin time, should be obtained as indicated by medical history. Pacemakers, automatic implanted cardioverter-defibrillators (AICDs), abdominal aortic aneurysm, orthopedic prostheses, and obesity are no longer considered contraindications.

Patients with pacemakers can be treated safely if the pacemaker is pectorally placed and the following precautions are observed.[175-177] Pacemaker programmability should be established before the treatment, and the pacemaker should be switched to a nondemand mode in case the shock waves interfere with pacemaker function. Alternative means of pacing should be available. Although most pacemakers located pectorally are at a safe distance from the blast path, some may be damaged. Weber and coworkers[175] examined 43 different pacemakers and found that three were affected. Dual-chamber pacemakers tend to be more sensitive to interference. Treatment should be started at a low energy level and gradually increased while observing pacemaker function.

Manufacturers of AICDs and lithotripters have considered an AICD a contraindication for lithotripsy; however, patients with AICDs have been treated successfully with lithotripsy.[176] AICD devices should be shut off immediately before lithotripsy, with an alternative means of defibrillating available, and then reactivated immediately after treatment.[178]

Patients with small aortic aneurysms have been treated safely, provided that the stone is not close to the aneurysm. Orthopedic prostheses, such as hip prostheses and even Harrington rods, are not a problem if they are not in the blast path, which is usually the case. Positioning of obese patients may be problematic at times. Not only do extremely obese patients present anesthetic challenges related to obesity, but also focusing of the stone may be extremely difficult in the very obese. It is prudent for focusing of the stone to be attempted before administering any anesthetic in this high-risk population.

Open Radical Surgery in Urology

Radical surgery is the excision of a tumor or diseased organ and possibly adjacent structures, along with their blood supply and lymphatic drainage. These procedures are generally performed for patients with malignant rather than benign disease and may be lengthy with sudden and significant blood loss. Although the trend over the past decades has been from open to laparoscopic or robotic-assisted approaches, there are still cases where major open urologic procedures are indicated.

Radical Nephrectomy

The most common malignancy of the kidney is renal cell carcinoma, comprising 80% to 85% of all solid renal masses.[179] Because renal cell carcinoma is refractory to chemotherapy and radiation therapy, surgical resection or ablation can offer curative treatment of localized disease (Box 59.4). The procedure involves removal of the kidney, the ipsilateral adrenal gland, perinephric fat, and the surrounding fascia.

BOX 59.4 Anesthetic Implications of Radical Nephrectomy for Tumors

- 85%-90% are for renal cell cancer
- 5%-10% extension to the inferior vena cava and right atrium
- Large-bore intravenous access, A-line, internal jugular vein line (preferably on left side if inferior vena cava is involved)
- Paraneoplastic syndrome
- Hypercalcemia, eosinophilia; increased prolactin, erythropoietin, and glucocorticoids
- Occurs more frequently in men than women
- Chronic smoking history usually associated
- Coronary artery disease, chronic obstructive pulmonary disease
- Renal failure

Recently, resection of the ipsilateral adrenal gland has been reserved for patients with large upper-pole lesions or when the adrenal gland is enlarged or appears abnormal.[180] Partial nephrectomy (nephron-sparing surgery) is considered for patients with a solitary functional kidney, small lesions, or bilateral tumors or for patients with increased risk because of other diseases, such as diabetes or hypertension.[181,182] Nephron-sparing surgery in the treatment of renal cell carcinoma has been shown to have an equal curative potential as radical nephrectomy.[183]

With radical nephrectomy, significant cardiorespiratory changes attendant to the flank position are a concern. Respiratory changes include decreases in thoracic compliance, tidal volume, vital capacity, and functional residual capacity. Dependent atelectasis is common and can lead to hypoxemia. Pneumothorax may occur and can have significant respiratory and hemodynamic consequences intraoperatively. It is common to see a decrease in blood pressure when the kidney rest is raised. This decrease is usually due to compression of the inferior vena cava. In addition, hepatic encroachment on the vena cava and mediastinal shift may reduce venous return and stroke volume further. Cervical plexus, brachial plexus, and common peroneal neuropathies can occur because of stretch or compression of nerves in the lateral position.

In 5% to 10% of patients with renal cell carcinoma, the tumor extends into the renal vein and the inferior vena cava and right atrium. Tumor extension into the inferior vena cava and atrium occurs more frequently with right-sided renal cell carcinoma. Several problems can occur in these patients, ranging from circulatory failure as a result of complete occlusion of the vena cava by tumor to acute pulmonary embolization of tumor fragments during surgery. To operate on these patients safely, the extent of the lesion must be defined preoperatively. Cardiopulmonary bypass may be required. CVP in such cases might not reflect intravascular volume accurately, because venous return through the inferior vena cava can be impaired by thrombus; hence intraoperative transesophageal echocardiography may be of value.[184] A decrease in venous return also predisposes the patient to hypotension during induction of anesthesia. Venous obstruction can lead to dilation of the epidural veins and the development of abdominal wall and retroperitoneal collaterals. The emphasis should center on appropriate preoperative preparation, which is possible only when the full extent of the lesion has been defined.[185]

Radical Cystectomy

Bladder cancer is the fourth most common cancer in men and twelfth in women in United States.[186] Radical cystectomy with regional pelvic lymph node dissection is the surgical treatment of choice for the management of nonmetastatic muscle-invasive bladder cancer and the highest-risk nonmuscle-invasive bladder cancer. Radical cystectomy with urinary diversion is considered one of the most complex urologic procedures and involves removal of the entire bladder, the distal ureters, and lymph nodes, as well as the prostate, and seminal vesicles in men or urethra, adjacent vagina, and uterus in women. For urinary diversion, either an orthotopic neobladder or ileal conduit are commonly created.[187] This procedure is associated with significant morbidity and prolonged hospital stays. One large study looking at a data registry in England of 2537 patients with an open radical cystectomy over a 2-year period (2014-2015) reported a median blood loss of 500 to 1000 mL with a transfusion rate of 21.8%.[188] In the Surveillance, Epidemiology, and End Results-Medicare database of 5207 patients who underwent radical cystectomy between 1991 and 2009 mortality at 30 days in patients older than 65 years old was 5.2%.[189] Complications of this procedure include urinary extravasation, intestinal anastomotic leaks, postoperative ileus, postoperative infections, and venothromboembolism. Enhanced recovery after surgery (ERAS) protocols have shown improved emotional and physical recovery.[190] In addition, patients given alvimopan, a peripherally acting μ-opioid receptor antagonist, showed significantly quicker bowel recovery.[191]

As with any major operation with the potential for significant blood loss, adequate intravenous access and placement of an arterial line are essential. General endotracheal anesthesia is indicated with consideration of a general/epidural technique for postoperative analgesia and/or the use of ERAS protocols for these procedures. The volume of urinary output cannot be used as a measure of fluid status due to its absence; however, the operative team can observe whether urine flow is noted at the clipped ends of the ureters. Blood lactate levels can be monitored to determine adequate organ perfusion. Placement of a central venous line for resuscitative purposes might be considered when there is anticipation of major blood loss.[192] The implementation of ERAS protocols for open RC with urinary diversion has demonstrated expedited bowel function recovery and shortened hospital stays without an increase in hospital readmission rates.[193]

Radical Prostatectomy

Prostate cancer is the most commonly diagnosed cancer in men and the second leading cause of cancer death of men in the United States.[186] Localized prostate cancer is treated by either radiation therapy or radical prostatectomy (Box 59.5). Radical prostatectomy has become more commonly performed because of routine prostate-specific antigen

BOX 59.5 **Anesthetic Implications of Radical Prostatectomy**

- Disease of the elderly
- Coronary artery disease, chronic obstructive pulmonary disease, and renal dysfunction
- Significant blood loss
- Wide-bore intravenous access and invasive monitoring
- Acute normovolemic hemodilution versus autologous blood donation
- Hyperextended position
- Nerve injuries, soft tissue injury, joint dislocations
- Venous air embolism
- Anesthetic management
  - Benefits of regional anesthesia versus general anesthesia debated
  - Not known to influence mortality
  - Epidural anesthesia with spontaneous ventilation decreases blood loss
  - General or combined anesthesia with intermittent positive pressure ventilation increases blood loss

testing in men older than 50 years and popularization of the nerve-sparing surgery to reduce the risk of impotence. Although originally described in 1905 via the transperineal approach, the retropubic approach is currently more commonly performed. The prostate, the ejaculatory ducts, the seminal vesicles, and part of the bladder neck are removed along with the pelvic lymph nodes.

Traditionally, the procedure was performed by open laparotomy, but robotic-assisted surgery is replacing that technique with increasing frequency. A potential intraoperative problem with open radical prostatectomy is hemorrhage and rapid blood loss requiring blood transfusion; therefore large bore intravenous access is recommended. Autologous predonation, preoperative recombinant erythropoietin therapy, intraoperative isovolemic hemodilution, and blood cell salvage are commonly practiced to reduce the patient's exposure to allogeneic blood. Early postoperative complications, including deep vein thrombosis, pulmonary embolism, hematoma, seroma, and wound infection, occur in 0.5% to 2% of cases.[194] Late complications include incontinence, impotence, and bladder neck contracture.[195] Patients undergoing radical prostatectomy are placed supine in Trendelenburg position with the back extended, which places the pubis above the head. Air embolism from the prostatic fossa caused by a gravitational gradient between the prostatic veins and the heart has been reported.[196]

Comparison of Anesthetic Techniques for Radical Prostatectomy

Epidural anesthesia, spinal anesthesia, general anesthesia, and combined epidural and general anesthesia have been used for this surgery. For the epidural component of combined techniques, a thoracic or a lumbar approach to catheter placement has been used, and spontaneous ventilation or intermittent positive pressure ventilation (IPPV) has been used for the general anesthesia component. Many investigators have reported their findings in comparing the four anesthetic techniques for radical retropubic prostatectomy,[197-200] and certain trends emerge.

Intraoperative blood loss is significantly decreased if epidural anesthesia or a combined epidural and general anesthetic with spontaneous ventilation is used. In one study, blood loss in the general anesthesia and the combined anesthesia group with IPPV was significantly more than in the epidural anesthesia group, despite little difference in arterial pressure among the three groups.[197] It was postulated that the increased venous pressure as a result of IPPV was the most likely cause of increased bleeding in the general and the combined anesthesia groups during radical prostatectomy. Previous studies have shown that central and peripheral venous pressures are lower in patients during spontaneous ventilation under epidural anesthesia or combined epidural-general anesthesia than in patients receiving IPPV during general anesthesia.[201] Epidural anesthesia alone or in combination with a general anesthetic decreases the risk of thromboembolism,[202] decreases postoperative pain and analgesic requirements,[203] and speeds recovery of bowel function. The length of stay and the cost of hospitalization can be decreased with the judicial use of epidural anesthesia and adherence to established clinical pathways.[204,205] In one study, 80% of patients were satisfactorily discharged after 1 day and the mean length of stay was 1.34 days.[206]

Possible differences in patient outcome with general versus epidural anesthesia are not clear. Local practices are therefore based on the preferences of the urologist, anesthesiologist, and patient.

Robotic and Laparoscopic Surgery in Urology

The advantages of laparoscopic surgery over conventional open surgery, including decreased hospital stay, improved visualization, decreased blood loss, expedited recovery time, reduced postoperative pain, and improved cosmetic outcomes, have been well described. The introduction of robotic-assisted surgery offers further enhancements of control and mobility to the surgeon but with increased cost and controversy over whether there is a clear benefit regarding reduction in morbidity and mortality compared with laparoscopic techniques.[207] The use of robots in urologic surgery has been extended to radical prostatectomy, radical cystectomy, pyeloplasty, and renal and adrenal surgery in adults and children.

Anesthetic concerns of robotic-assisted surgery include the length of surgical time, intravenous fluid management, and positioning. The most frequent reported complications are peripheral neuropathies, corneal abrasions, vascular complications including compartment syndrome, rhabdomyolysis, thromboembolic disease, and the effects of edema.[208] In addition, significant anesthetic concerns for urologic minimally invasive surgeries surround the physiologic effects of pneumoperitoneum, the use of lateral decubitus, and steep head down tilt (SHDT) positions, as well as restricted access secondary to the robot and the robotic arms and extensions over the patient.

Although all the conventional complications and concerns associated with laparoscopy and robotic-assisted procedures are applicable to urologic procedures, two unique problems are identified. First, because the urogenital system is mainly retroperitoneal, the large retroperitoneal space and its communications with the thorax and subcutaneous tissue are exposed to the insufflated carbon dioxide. Significant subcutaneous emphysema can occur in these patients and may extend all the way up to the head and neck.[195] The upper airway is at risk for compromise in the most severe cases because of pharyngeal swelling secondary to submucosal carbon dioxide. This complication should be kept in mind before extubation of the trachea in these patients. Second, the procedures can be lengthy, allowing for sufficient absorption of carbon dioxide to result in acidemia and marked acidosis.[195] Because of significant increases in intraabdominal and intrathoracic pressure as a result of insufflated carbon dioxide, use of SHDT position in some cases, and the long duration of procedures, general anesthesia with controlled ventilation may be the method of choice. Despite adequate intravascular hydration, intraoperative oliguria may occur and can be followed by diuresis in the immediate postoperative period. Increased perirenal pressure exerted by the insufflated gas in the retroperitoneal space causes an increase in renal vascular resistance with direct compression of the renal parenchyma and renal vein. This causes a release of renin and aldosterone, along with antidiuretic hormone, which temporarily decreases renal blood flow, renal function, and urinary output.[209]

Ventilatory and respiratory concerns of pneumoperitoneum include decreased compliance, increased airway pressures,

BOX 59.6 **Pneumoperitoneum-Related Physiologic Changes**

Increased	Decreased
Systemic vascular resistance	Cardiac output
Blood pressure	Functional residual capacity
Peak airway pressure	Lung compliance
Ventilation-perfusion mismatch	Renal blood flow
Intracranial pressure	Glomerular filtration rate
	Splanchnic blood flow

and increased ventilation-perfusion mismatch. Application of positive end-expiratory pressure improves oxygenation in these patients.[210] Hypercapnia develops within 15 to 30 minutes of carbon dioxide insufflation with resultant hypercarbia, acidosis, tachycardia, dysrhythmias, and other deleterious hemodynamic and CNS effects.[211] Increase in mechanical ventilation can obviate these changes in most patients, and the majority of healthy patients tolerate the changes even though they are clinically significant. Extraperitoneal insufflation of carbon dioxide is associated with larger increases in arterial PCO_2 than in intraperitoneal insufflation.[212] Hemodynamic changes observed during initiation of pneumoperitoneum (Box 59.6) include increases in systemic vascular resistance and mean arterial pressure. These changes are caused by increased intraabdominal pressure compressing the aorta and increasing afterload.[213] Cardiac output has been observed to decrease with insufflation.[214,215] Variable changes in heart rate have been reported. Reflex bradycardia has been observed to occur with establishment of pneumoperitoneum probably related to peritoneal stretch and vagal stimulation.[216]

Robotic-Assisted Radical Prostatectomy

Robotic-assisted radical prostatectomy (RARP) has become the second most performed robotic-assisted surgical procedure worldwide.[217] Anesthetic concerns are primarily related to the use of pneumoperitoneum in the steep Trendelenburg position. For RARP the patient is placed in the dorsal lithotomy position, arms tucked at the side of the table, and drapes placed over the patient which limits the anesthesiologist's ability to access the patient. Pneumoperitoneum is initiated, and the patient is then placed in a 30- to 45-degree Trendelenburg position. With limited access to the patient after draping; intravascular lines, monitors, and patient protective devices need to be placed and secured beforehand. Once the robot is positioned over the patient with its arms attached (docked) to the ports; movement of the patient and/or cardiopulmonary resuscitative measures cannot be performed unless the robot is first undocked.[218] Patient movement during the surgery could result in visceral or vascular injury. Constant assessment of the degree of muscle relaxation intraoperatively is recommended. Because of the limited access and duration of the procedure, careful attention should also be given to pressure areas of the arms and legs to avoid ulnar neuropathy and lateral femoral cutaneous nerve injury.[214]

Physiologic changes resulting from SHDT position include hemodynamic effects such as decreased perfusion pressure of lower extremities, increased mean arterial pressure at the circle of Willis, increased central blood volume, decreased cardiac output, and a decreased perfusion of vital organs in a normovolemic patient. Increased myocardial oxygen consumption, ischemia, dysrhythmias, and decreased oxygen delivery are potential risks in patients with cardiac disease. Despite an observed twofold to threefold increase of right- and left-sided filling pressures in ASA I and II patients during RARP, Lestar and colleagues[219] observed no significant changes in cardiac performance. Respiratory effects of SHDT including decreased compliance, reduced vital capacity and functional residual capacity, 20% decrease in lung volumes, and ventilation-perfusion mismatch compound the effects of pneumoperitoneum. Pulmonary congestion and edema have been reported in susceptible patients. Facial, pharyngeal, and laryngeal edema may also occur with the SHDT position. Chemosis (conjunctival edema) is common in RARP but is usually self-limiting once the patient is taken out of the steep Trendelenburg position. If facial and/or conjunctival edema is noted at the end of the procedure, the anesthesiologist should have a high index of suspicion for the presence of laryngeal edema. A transient increase in serum creatinine secondary to pneumoperitoneum during robotic prostatectomy has been reported.[220] In the Trendelenburg position, patients with a history of reflux have an increased risk of regurgitation of gastric contents and aspiration.

Other significant effects of SHDT include increased intracranial pressure, increased intraocular pressure (IOP), venous air embolism, brachial plexopathy, arthralgias, compartment syndrome, and finger injuries. Perioperative assessment of the function of a patient with a ventriculoperitoneal shunt scheduled for any laparoscopic procedure is recommended.[221] Issues arising from increased intracranial pressure or consequences of a malfunctioning shunt with pneumoperitoneum in SHDT position need to be recognized. Kalmar and associates concluded patients overall clinically tolerated the influence of prolonged SHDT position with CO_2 pneumoperitoneum on cardiovascular, cerebrovascular (including cerebral perfusion pressure and oxygenation), and respiratory homeostasis during robotic prostatectomy.[222]

Significant increases in IOP have been reported in robotic prostatectomy with the steep Trendenburg position, but the clinical significance is unknown.[223] However, of concern are patients with primary open angle glaucoma who have decreased outflow through the trabecular network, which causes IOP. Two patients with severe glaucoma were advised against proceeding with a RARP in the steep Trendelenburg position and instead opted for open radical prostatectomies in the supine position.[224] However, another patient with severe glaucoma undergoing RARP was treated intraoperatively with acetazolamide and mannitol to manage the increase in IOP.[225] In addition, there are reports of at least six cases of postoperative visual loss secondary to ischemic optic neuropathy following radical prostatectomy: three open and three robot-assisted prostatectomies.[226] Limiting time in the steep Trendelenburg position and reducing the volume of intravenous fluids administered may decrease the risk of this devastating complication.[227]

With the exception of one study, the literature suggests that compared with retropubic radical prostatectomy, RARP is associated with a reduction in blood loss.[228] Mild to moderate pain is expected postoperatively, and low pain scores of 0 to 4 have been reported after retropubic radical prostatectomy and RARP using preemptive analgesia with ketorolac given intraoperatively combined with rescue opiate or nonopiate analgesia.[229] Most patients are discharged home the day after surgery.

Robotic-Assisted Radical Cystectomy With Diversion

The ensuing popularity of robotic-assisted urologic procedures over the past few decades also gave rise to the first robotic-assisted radical cystectomy (RARC) with extracorporeal or intracorporeal neobladder formation as first described in 2003.[230,231] Since 2003 the use of RARC has increased substantially in the United States and globally, but there is controversy regarding the safety, efficacy, and cost effectiveness of the robotic approach.[232] A meta-analysis of four randomized controlled trials comparing RARC with extracorporeal urinary diversion with open radical cystectomy concluded that blood loss and wound complications were significantly lower in the RARC group; however, operating time was significantly longer with use of the robot. However, there was no significant difference between RARC and open radical cystectomy in perioperative morbidity, length of stay, positive surgical margin, lymph node yield, and positive lymph node status.[233] In a multicenter, retrospective review comparing RARC with extracorporeal to intracorporeal urinary diversion, the 90-day overall complication rate was not significantly different, but the incidence of gastrointestinal and infectious complications was significantly lower in patients in the intracorporeal group.[234] The intracorporeal technique has several advantages in that the bowel stays inside the abdomen, no hypothermia or loss of fluids via osmosis occurs, and there is decreased bleeding, decreased need for ureteral dissection, and decreased traction on the bowel and ureters.[235] The implementation of ERAS protocols has been shown to reduce the length of stay of patients undergoing RARC with intracorporeal urinary diversion.[236,237] Although the robotic approach may minimize complications, oncologic outcome has not improved over the past three decades, and surgical technique is unlikely to improve survival outcomes.[238]

As in RARP, the anesthetic concerns of RARC include management of SHDT and pneumoperitoneum with the patient in the dorsal lithotomy position, along with limited access to the patient. Epidural analgesia is generally not necessary, because RARC patients have reduced postoperative pain and early mobilization is encouraged. Although the usual intraoperative concerns of preventing hypothermia, hypoxemia, and hypovolemia while avoiding overhydration are present, there is the additional goal of avoiding opioid-based analgesics and their effects on bowel recovery.[239] The implementation of ERAS protocols helps to achieve the goal of limiting the use of postoperative opioids. In one study performed at a medical center with extensive experience in urologic surgery, 100 patients who underwent RARC with urinary diversion experienced operative times ranging from 4 to 12.9 hours, depending on the type of urinary diversion performed, and with reported blood losses of up to 1400 mL.[237] As a consequence, because these surgeries may be lengthy with the possibility of substantial blood loss, adequate intravenous access along with insertion of an arterial pressure line is recommended. Arterial blood gases may be obtained at regular intervals to assess the presence of either respiratory and/or metabolic acidosis. With long insufflation times of CO_2, respiratory acidosis can occur and should be managed according to end-tidal carbon dioxide values in tandem with $PaCO_2$. In addition, metabolic acidosis may occur (secondary to fluid restrictions) before and during the procedure and hypothermia, as a result of heat loss due to lengthy operative times or the insufflation of cold CO_2 gas.[240]

LAPAROSCOPIC NEPHRECTOMY

Laparoscopic nephrectomy is commonly used for radical and living donor nephrectomy. For radical nephrectomy, studies suggest that there are no significant differences in oncologic outcomes between open and laparoscopic procedures, although the laparoscopic technique, as discussed earlier, has the advantages of decreased morbidity, blood loss, postoperative analgesic requirements, and hospital length of stay.[241,242] In a large retrospective study of 23,753 patients from 2003 to 2015 comparing perioperative outcomes of robotic-assisted to laparoscopic radical nephrectomies for patients with renal masses, there were no differences in the rates of major complications or blood transfusions. However, the use of robotic-assisted nephrectomy increased over the course of the study, from 1.5% to 27% of cases by 2015; and was associated with prolonged operating times and higher hospital costs when compared with laparoscopic surgery.[243]

Two laparoscopic approaches are commonly used for nephrectomies: transperitoneal or retroperitoneal. The primary advantage of the transperitoneal laparoscopic approach is the greater working space offered for large renal tumors (≥10 cm),[244] whereas the retroperitoneal approach avoids transabdominal fatty tissue and allows for limited dissection of the kidney with direct access to the renal hilium.[245] The lateral or semilateral decubitis position with some degree of flexion, along with use of a cushioned beanbag, pillows, and axillary roll, is usually used for these procedures. Besides the usual possible complications from laparoscopic surgery (e.g., positioning injuries, subcutaneous emphysema, and CO_2 emboli), the occurrence of rhabdomyolysis is a concern after laparoscopic nephrectomy. Risk factors include prolonged surgical time, high body mass index, volume depletion, and use of the lateral decubitis position. Limiting the amount of flexion has been recommended to decrease the incidence of this complication.[246] Anesthetic considerations, other than the previously discussed physiologic effects of pneumoperitoneum, include adequate intravenous access, whereas insertion of an arterial line, CVP catheter, and/or transesophageal echocardiography may be reserved for selected high-risk patients.

Robotic-Assisted Partial Nephrectomy

Partial nephrectomy is the standard for the treatment of small renal masses (<4 cm) for the reasons previously discussed (see Radical Nephrectomy).[247] Surgical excision of these tumors has progressed from open radical nephrectomy to laparoscopic partial nephrectomy (LPN) and robotic partial nephrectomy (RPN). RPN has become the preferred technique because the learning curve for RPN is estimated to be 25 cases when compared with more than 200 cases for LPN.[248] Both LPN and RPN require the temporary clamping of the renal hilum to improve surgical visibility and reduce blood loss; however, to prevent AKI the warm ischemia time related to clamping should not exceed 30 minutes.[249,250] In a meta-analysis of 23 studies including 2240 patients, RPN when compared with LPN was found to have a lower conversion rate to open or radical surgery, a better postoperative estimated GFR, shorter warm ischemia time, lower estimated blood loss, and shorter length of hospital stay.[251,252]

Anesthetic concerns for RPN, as in laparoscopic nephrectomy, involve proper positioning and the use of pneumoperitoneum. To allow for unhindered robotic arm movement, the patient is placed in the lateral decubitis position, brought toward the edge of the operating table, and flexed approximately 15 degrees at the kidney.[253] Of concern with partial nephrectomy, there is a decrease in the number of functioning nephrons causing hyperfiltration of the remaining glomeruli. This increase in load to the remaining glomeruli leads to an increase in intraglomerular pressure causing injury to the kidneys in the short and long term. A retrospective study of AKI after partial nephrectomy found that the higher the intraoperative fluid administration, the greater the drop in the GFR postoperatively. RPN was found to be more tolerant of fluid administration than open or LPN. The authors postulated that the precision of the robot allows minimal handling of the remainder of the renal tissue and this may confer protection. Therefore judicious fluid administration is recommended during partial nephrectomy.[254]

Urogenital Pain Syndromes and Treatment

Pain syndromes of the urogenital system can be divided into those occurring in the immediate postoperative period, acute or chronic nonmalignant pain, and cancer-related pain. Treatment includes medications, neuraxial and regional nerve blocks, and neuromodulation or surgery. Choice of modality in the perioperative period must balance analgesia with side effect profile, particularly as common urologic surgeries become less invasive and focus shifts to fast-track surgeries and ERAS protocols.

POSTOPERATIVE PAIN AND TREATMENT

Inflammatory Pain

Pain after urogenital surgery is similar to other postoperative pain, occurring as a direct result of surgical manipulation and trauma. Acute pain is most commonly inflammatory and related to incision, retraction, and suturing. Mediators of inflammation are local and systemic, including bradykinins, serotonin, prostaglandins, histamine, leukotrienes, and cytokines.[255] Pain is worst in the first few days following surgery and generally improves rapidly with tissue healing.

Neuropathic Pain

Neuropathic pain may also exist postoperatively, mediated via neurogenic inflammation[256] or due to temporary or sustained pressure, stretch, or direct ligation of nerves. This pain can be immediate or develop over weeks to months as severed nerve endings regrow or are trapped in scar tissue and form neuromas. Pain is described as burning, pins-and-needles, electric, and radiating in a dermatomal or peripheral nerve distribution.

Postoperative Urinary Retention

Particularly with regard to urologic surgery, postoperative urinary retention (POUR) should be considered as a source of postoperative pain. Evaluation may be difficult due to neuraxial or regional block, residual effects of general anesthesia, or the diffuse nature of visceral pain. Risk factors include male gender; duration of surgery; amount of intravenous fluid given; concurrent neurologic disease; perineal surgery; use of anticholinergics, β-blockers, or adrenergic agents; and neuraxial local anesthetic or opioids.[257] In addition, high clinical suspicion is merited if pain is accompanied by signs of disparate autonomic changes, such as bradycardia and hypotension. Left untreated, POUR can result in bladder distension and adverse effects on long-term urodynamics. Prompt diagnosis, either clinically or via ultrasound, and bladder catheterization if indicated (postvoid residual >600 mL) can prevent sequelae.

Enhanced Recovery After Surgery

Urologic procedures such as radical cystectomy or radical prostatectomy were traditionally large blood-loss procedures with prolonged recoveries and significant associated postoperative pain. As a result, most pain management algorithms included neuraxial and regional blocks and minimized use of nonsteroidal antiinflammatory drugs (NSAIDs) to decrease bleeding risks. Indeed, various studies have demonstrated the successful use of epidural anesthesia[259] or rectal sheath catheters[260] in open radical cystectomy. However, with a move toward laparoscopic and robotic-assisted techniques, these procedures have become less invasive and the focus has shifted to early mobilization, recovery, and hospital discharge. These goals are often packaged as part of a perioperative ERAS protocol. From a pain management standpoint, the primary goal of management is use of multimodal analgesia to minimize opioid use and side effects, primarily ileus. Prior to ERAS implementation, postoperative ileus, or lack of gastrointestinal motility, was the most common cause for prolonged hospitalization and readmission, occurring in 12% to 25% of patients after radical cystectomy.[261]

To promote early mobilization, most protocols currently advocate the use of scheduled intravenous or orally administered acetaminophen or paracetamol and of NSAIDs for breakthrough pain, as well as the possible inclusion of gabapentinoids[262] and the use of single-shot neuraxial or regional techniques in place of epidural catheters.[263]

CHRONIC POSTSURGICAL PAIN

In most cases, postoperative pain resolves quickly, over days to weeks, and can be managed with oral opioid or nonopioid analgesics; however, for some patients, gastrointestinal, respiratory, or cognitive side effects may prohibit their effective use. Furthermore, a subset of patients develop chronic postsurgical pain (CPSP), defined by the International Association for the Study of Pain as postoperative pain lasting more than 2 months and not explained by preexisting pain or ongoing trauma.[264] Risk factors for CPSP are well described across many types of surgery and the incidence can be high, with 20% to 50% of patients reporting persistent chronic pain of any type and 2% to 10% reporting severe disabling pain that ranks from 5 to 10 on the pain intensity numeric rating scale.[265] The biggest predictor of CPSP is poorly controlled acute postoperative pain,[266] which has led to a focus on the immediate perioperative period.

Perioperative Management Considerations

Specific to renal compromise, meperidine and morphine should be avoided due to accumulation of renal-excreted metabolites including normeperidine and morphine-3-glucuronide, which lower the seizure threshold, and morphine-6-glucuronide, which maintains activity at the μ-opioid receptor and can accumulate to toxic levels if insufficient renal clearance. Opioids, particularly via the neuraxial route, can result in urinary retention. Gabapentinoids, if used, are renally excreted and must be dose adjusted based on creatinine clearance. The antiprostaglandin effect of NSAIDs can decrease renal blood flow or increase bleeding risk in susceptible patients.

ACUTE OR CHRONIC NONMALIGNANT PAIN

Benign Renal Masses

Flank pain is a common symptom in adults with angiomyolipomas, which consist of abnormal growth of blood vessels, smooth muscle, and fat. This benign neoplasm can create a mass effect that affects renal function, and acute worsening of pain should raise suspicion for rupture and hematoma formation. Angiomyolipomas can be associated with tuberous sclerosis but are more commonly found in otherwise healthy individuals. Treatment involves management of symptoms with acetaminophen and antineuropathic agents. Care should be taken with NSAID use, because renal function may be compromised.

Polycystic Kidney Disease

Polycystic kidney disease is most often inherited in an autosomal dominant manner and can lead to massive enlargement of the kidneys with compromised renal function. Renal pain is caused by distention of the cysts and stretching of Gerota fascia. Hemorrhage into the cysts, rupture of the cysts, or infection can produce acute exacerbation of pain. Percutaneous drainage of renal cysts may relieve these symptoms. Opioids can be appropriate in the acute phase.

NEPHROLITHIASIS

Obstruction of the urinary tract causes severe, spasmodic pain in the flank. Pain from the upper third of the ureter may be referred to the lower abdomen and back, pain from the middle third to the iliac fossa, and pain from the lower third to the suprapubic and groin area. Minimal fluid intake and a high concentration of stone-forming salts can predispose to nephrolithiasis. Renal colic, hematuria, and radioopaque stones (70%-75% of calculi) on radiography or noncontrast CT confirms the diagnosis.[267] Opioids and NSAIDs are appropriate for severe, acute symptoms. Despite widespread use, intravenous hydration has not demonstrated benefit.

INFECTIOUS RENAL DISEASE

Infectious renal diseases producing flank pain include pyelonephritis and perinephric abscess. Fever is an important associated finding that suggests the presence of infection. Because the kidneys are retroperitoneal organs, peritoneal signs are generally absent. Differential diagnosis must include inflammatory or infectious disease of surrounding organs, including lower lobe pneumonia, pancreatitis, appendicitis, and cholecystitis. Oral or parenteral opioids are usually effective for pain control in the acute setting. Systemic antibiotics are curative in most cases, although surgical intervention may be warranted and a focal nidus for infection (stone, urethral reflux, recurrent urinary tract infection) should be pursued.

INTERSTITIAL CYSTITIS

Interstitial cystitis is a chronic pain condition marked by suprapubic pain related to bladder filling and symptoms of increased frequency and urgency in the absence of infection or malignancy.[268] Pathologic features of interstitial cystitis that may be evident but are not necessary to make the diagnosis include Hunner ulcers (discrete, bleeding areas on the bladder wall) and glomerulations (petechial bleeding after distension). The proposed pathophysiology is thought to be a deficient glycosaminoglycan layer that allows increased permeability of the bladder wall, resulting in inflammation and pain. Options for pain control include pentosan polysulfate (intended to repair the glycosaminoglycan layer), antineuropathics, antihistamines, dimethyl sulfoxide instillation, and sacral nerve stimulators.

NEURALGIAS

Pseudorenal pain syndromes can be caused by entrapment of nerves colocalized with the urinary system in the lower abdomen and groin. Entrapment can occur as the result of trauma or surgical injury or can be idiopathic. Neuralgia of the genitofemoral nerve is common after hernia surgery given its close proximity and variable relation to the spermatic cord. Pain radiates to the inguinal ligament via the femoral branch and to the testicle via the genital branch. Injury to the iliohypogastric or ilioinguinal nerves can occur with lower abdominal incisions or trocar placement for laparoscopy, resulting in neuralgia radiating to the lower abdomen and groin. Pudendal neuralgia can occur with damage to the pudendal nerve along its intrapelvic or extrapelvic course and results in pain of the external genitalia and perineum. Pain sensation is generally neuropathic in these conditions, and dermatomal testing will often reveal sensory deficits. Nerve blocks can be performed under ultrasound guidance[269] to help establish the diagnosis, differentiate from urogenital pain, and for therapeutic benefit. Antineuropathic agents can also be of help should nerve injury be confirmed.

CHRONIC PROSTATITIS

Acute prostatitis is usually caused by a bacterial infection and responds to antibiotic therapy. Chronic prostatitis is often referred to as chronic pelvic pain syndrome or chronic abacterial prostatitis to reflect that there is little certainty that inflammation or infection of the prostate is responsible for symptoms.[270] Symptoms include genital/pelvic pain and sexual dysfunction, often accompanied by lower urinary tract symptoms. Moderate improvement has been noted with antibiotics, α-blockers, antiandrogens, NSAIDS, and pelvic floor physiotherapy.

PRIAPISM

Priapism is a prolonged erection more than 4 hours in duration and can be ischemic (venoocclusive) or nonischemic (arterial). The former represents an acute emergency, and prompt therapy should be instituted to control pain and prevent subsequent impotence from fibrosis of the corpora cavernosa. Treatment consists of a penile dorsal nerve block performed at the pubic symphysis with needle entry into the subpubic space, performed with local anesthetic without epinephrine, after which aspiration of blood or intercavernosal phenylephrine can be performed.[271] Nonischemic priapism is most commonly posttraumatic and results from creation of an arteriolar-sinusoidal fistula. This type of priapism is typically not as painful and responds to conservative management. Sickle cell priapism is treated with hydration, alkalinization, and blood transfusion to increase hemoglobin to more than 10 mg/dL.

CHRONIC PELVIC PAIN IN WOMEN

Chronic dysmenorrhea can be addressed with ovulation suppression or use of NSAIDs, which decrease uterine lining thickness and cramping via an antiprostaglandin effect.[272] Chronic pelvic pain may also be due to endometriosis, pelvic venous congestion, adhesions, or pelvic inflammatory disease—each of which is most responsive to correction of the underlying disorder for relief of pain. Vulvodynia is a chronic pain condition associated with sexual inactivity or dysfunction due to vulvar pain. Some success with tricyclic antidepressants (TCAs), sitz baths, local estrogen creams, and pudendal nerve blocks has been reported. Vaginismus is associated with increased tone of the muscles of the pelvic floor (pubococcygeus and levator ani) producing spasms and painful sexual dysfunction. Dyspareunia is defined as recurrent and persistent genital pain before or after intercourse not solely explained by infection, trauma, lubrication, or vaginismus. Psychological factors often play a major role and a thorough history should be obtained because there is often a concomitant history of sexual abuse. Treatment involves pelvic floor physiotherapy and desensitization techniques.

TESTICULAR PAIN

Testicular pain can be the result of trauma, torsion, or infection. Trauma or torsion necessitate immediate restoration of blood flow and emergent surgical exploration is the treatment of choice. Orchitis or epididymitis should be suspected based on a thorough history and if signs of localized or systemic infection accompany pain. Tumors of the testis are most often malignant; however, extratesticular tumors within the scrotum are usually benign. Testicular tumors usually present as a painless testicular mass. Pain is a late sign and is usually described as a dull ache or heaviness due to mass effect.

MEDICATIONS

As with most chronic pain, medication use and risk and benefit must be judiciously weighed. Low-risk, high-yield medications such as topical agents (lidocaine, capsaicin), acetaminophen, and NSAIDs are usually first line treatments, particularly if pain is episodic or infrequent. Antineuropathic agents (gabapentinoids, selective norepinephrine reuptake inhibitors, TCAs) can be useful for prophylaxis, and certain secondary effects can be useful for particular pain conditions (e.g., the anticholinergic effect of a TCA for bladder spasm). Opioids are usually indicated only for acute flares, such as passing of an obstructing stone, and there is little evidence to validate their long-term use.

NERVE BLOCKS AND NEUROMODULATION

When possible, nerves involved with transmission of pain should be identified and treated individually. Treatment can include diagnostic nerve blocks, selective nerve root blocks, therapeutic nerve blocks, pulsed radiofrequency neuromodulation of peripheral nerves, dorsal root ganglia stimulation, cryoablation, radiofrequency ablation, chemoneurolysis, and implantable peripheral field stimulation.[273] Identifying the nerve that is most likely to be injured is the first step in pursuing an interventional approach. Ultrasound guidance offers several advantages that make it highly suited for diagnosing and treating urogenital nerve pain. The machines are portable, there is no radiation exposure, and many of the commonly affected nerves are located superficially. An initial block of the affected nerve using a low volume of local anesthetic can be performed with confirmation of sensory block in the expected distribution. If this block relieves the patient's usual pain, then neuralgia in this distribution is the likely diagnosis.[269] Urogenital pain often occurs between the abdomen and thigh, and the nerves supplying the skin and structures in this area are referred to as "border nerves"—the ilioinguinal, iliohypogastric, genitofemoral, and lateral femoral cutaneous nerves arising from the T12-L3 anterior rami as they form the upper lumbar plexus—as well as the pudendal nerve arising from S2-4.

CANCER-RELATED PAIN

Pediatric Tumors

Wilms tumor (nephroblastoma) generally occurs unilaterally and is painless on initial presentation. It may be associated with congenital malformations such as Beckwith-Wiedemann syndrome. Treatment consists of surgical resection most often supplemented by chemotherapy because the tumor is quite responsive to this modality. Perioperative pain may be addressed with epidural anesthesia, acetaminophen, and opioids. Chemotherapy-induced neuropathy, should it occur, can best be treated with antineuropathic agents.

Renal Cell Carcinoma

Renal cell carcinoma is described as having a classic triad of hematuria, flank pain, and renal mass; however, pain is often a late presentation and may indicate metastatic disease. In cases of metastasis, prognosis is often poor and pain widespread. Early consideration of an intrathecal catheter for continuous delivery of opioids, local anesthetic, or ziconitide can improve patient quality of life. Flank pain may be due to stretching of Gerota fascia, and metastasis is primarily local along the renal vein and inferior vena cava or into the intercostal nerves, which produces segmental neuralgia. In these cases, intercostal nerve blocks and neurolysis can be of use and accomplished under fluoroscopic or ultrasound guidance, most commonly with alcohol or phenol.

Bladder Cancer

The most common urothelial tumor is transitional cell carcinoma of the bladder. Painless hematuria is the most common manifestation, although patients may complain of bladder irritability if there is involvement of the muscular layers. Surgical treatment includes fulguration, transurethral resection, or cystectomy. Pain control is best accomplished with NSAIDs, acetaminophen, opioids, and neuromodulatory agents.

Prostate Cancer

Adenocarcinoma of the prostate is the most common cancer in men and is usually painless, discovered incidentally through routine physical examination. Epidural analgesia can be of use for acute pain control if brachytherapy with seeding is part of treatment. Lumbar or sacral pain with prostatic cancer may be a sign of metastatic disease to bone, which may respond to palliative radiation.

Uterine and Cervical Cancer

Uterine cancer usually presents as irregular bleeding and is associated with increasing age, obesity, nonchildbearing, and hormone therapy. Pain is commonly a late finding, owing to mass effect or invasion into the myometrium. Cervical cancer is generally discovered early through routine vaginal Pap testing, and its incidence has decreased with use of childhood vaccination for specific human papillomavirus strains. However, when present, dyspareunia is a common finding.

Neurolysis

Sympathetic innervation of the uterus and cervix is via the inferior hypogastric plexus, lying within the presacral tissues medial to the foramina sacralia on either side of the rectum, ventral to the S2, S3, and S4 spinal segments. The plexus can be accessed via a transsacral approach,[274] and neurolysis can be performed, although particular care is warranted given close proximity to motor nerve roots.

The pelvic viscera in men (the urogenital organs, distal colon, and rectum) are supplied by afferent fibers from the distal lumbar sympathetic chain via the superior hypogastric plexus, a retroperitoneal structure situated along the anterior surface of the L5 and S1 vertebrae. Visceral innervation follows these fibers, and interruption of these pathways can be achieved with a superior hypogastric plexus block using fluoroscopic or CT guidance and instillation of phenol or ethanol for neurolysis.[275]

The ganglion impar is another promising target for neurolysis, supplying mixed somatic, autonomic, and visceral fibers to the distal urethra, vulva, perineum, and distal third of the vagina. It can be blocked along the anterior surface of the sacrococcygeal junction, most commonly under fluoroscopic guidance.

Alternatively, peripheral nerve ablation can be performed using a variety of techniques. Ablation should not be performed on any nerves with a significant motor component because weakness will occur. Fortunately, the “border nerves” are primarily sensory; however, neurolysis often creates an area of desensitized skin, which can be bothersome for certain patients and may progress to anesthesia dolorosa, a feared complication manifested by pain in the area despite numbness to stimulation. Nonetheless, these approaches may be of significant benefit in appropriate cases and after full discussion of risks and benefits with the patient. Ablation may be performed with injection of a chemical neurolytic, such as phenol or dehydrated alcohol. Radiofrequency ablation creates a thermal lesion at 80°C along the active needle tip. Cryoablation creates a supercooled −70°C “ice ball” around the neural sheath, which leads to decreased transmission via wallerian degeneration. Case reports and series have shown promising results with decreased pain and analgesic requirements.

Intrathecal Medications

If intractable pain persists despite optimized oral or intravenous therapy, a single shot or tunneled intrathecal catheter trial can be performed and an implantable drug delivery system should be considered. Continuous intrathecal infusions minimize fluctuation of drug levels in cerebrospinal fluid and allow for significant analgesia and use of spinal adjuncts (local anesthetic, ziconitide) in addition to opioids with significantly lessened dose-limiting side effects.

In summary, perioperative pain syndromes of the urogenital system and those related to pain from malignant or nonmalignant disease require prompt attention, a comprehensive assessment, and consideration of multimodal early intervention including treatment with nonopioid or opioid medications, neuraxial and regional nerve blocks, and neuromodulation or surgery when appropriate.[276–278]

Anesthesia for Abdominal Organ Transplantation

CHRISTOPHER L. WRAY, JOHN R. KLINCK, and
RANDOLPH H. STEADMAN

KEY POINTS

- Survival after abdominal organ transplantation continues to improve.
- The imbalance between organ supply and demand is increasing as new indications emerge and transplantation is offered to growing numbers of older candidates.
- To increase the supply of organs, living donors and extended criteria deceased donors are being used more frequently.
- Evolving organ preservation techniques employing graft perfusion offer the promise of improved outcomes with marginal organs, potentially enlarging the organ supply.
- Knowledge of the pathophysiologic changes associated with end-stage disease is required to provide optimal care for patients undergoing transplant surgery.
- The kidney is the most frequently transplanted organ.
- Kidney transplant recipients are older and are more likely to have chronic illnesses than in the past.
- The perioperative and long-term risk of cardiovascular disease is increased in patients with end-stage renal disease.
- Maintenance of renal perfusion pressure in the perioperative period is critical for kidney graft function.
- Liver transplant recipients are older in age and have more comorbidities than in the past.
- The Model for End-stage Liver Disease (MELD) score prioritizes candidates for organ allocation in the United States.
- The pathophysiologic changes associated with liver disease affect nearly every organ system.
- Intraoperative care of liver transplantation recipients requires preparation for massive transfusion, management of coagulation abnormalities, and hemodynamic instability.
- Pancreatic transplantation is definitive treatment for diabetes mellitus.
- Pancreatic transplants are performed simultaneously with kidney transplantation (SPK), after kidney transplantation (PAK), or alone (PTA).
- Patients under 50 years with diabetes and end-stage renal disease benefit from SPK; however, more patients over age 50 and those with type 2 diabetes are now undergoing pancreas transplantation.
- In pancreatic transplant recipients, frequent monitoring of blood glucose concentrations is required during the perioperative period.
- Diabetic patients are at significant risk for cardiovascular disease.

Solid organ transplantation continues to grow worldwide. The success of transplantation over the past decades corresponds to improved survival for recipients. Increasingly, indications for transplantation have broadened. Patients with conditions previously considered contraindications, such as advanced age and some types of cardiopulmonary disease, are no longer precluded from transplantation.

Based on global data, 126,670 organs were transplanted in 2015, with a steady increase in yearly transplant activity over the past 5 years (Fig. 60.1).[1] In the United States there were 33,610 organ transplants performed in 2016; transplant volumes have increased annually in the United States as well.[2] In the United States and worldwide, the kidney is the most transplanted organ followed by the liver (Figs. 60.2 and 60.3).

Despite an encouraging trend in transplant volume, the number of patients who could benefit from transplantation far exceeds those who receive an organ. The imbalance between graft supply and demand is the major factor limiting organ transplantation in all countries. Solutions to organ shortage include living donor transplantation, which is used more commonly for kidney than liver transplantation. Other strategies include the use of extended criteria donors, including grafts from marginal donors declared brain dead (donation after brain death) and from donors dying from cardiac arrest (donation after cardiac death). These are discussed in detail elsewhere.

The evaluation of patients for transplantation varies among transplant centers, but the goals are similar. These include ascertaining that: (1) transplantation is indicated for the management of the prospective recipient, (2) comorbidities do not preclude transplantation, and (3) emotional and social resources permit a major surgery and its associated rehabilitation, including compliance with long-term immunosuppression therapy. The center's transplant selection committee typically consists of physicians (nephrologist and hepatologist for kidney and liver transplantation, respectively), transplant surgeon, psychiatrist, dietitian, social worker, and additional consultants as indicated. Anesthesiologists consult on high-risk candidates as agreed by local protocol. These include those with significant cardiovascular or respiratory comorbidities, poor nutritional or functional status, multiorgan failure, limited vascular access, or known anesthetic risks.

Reasons to deny transplantation vary among transplant centers, although in liver transplantation American Association for the Study of Liver Diseases guidelines and international consensus would mandate predicted 5-year survival greater than 40% to 60%. Critically ill patients receiving life support, vasopressors, or dialysis have decreased posttransplant survival.[3] Additional comorbidities can exacerbate the risk to a level that may be unacceptable to some centers. These may include significant coronary artery disease (CAD), moderate or severe pulmonary hypertension, metastatic disease, uncontrolled intracranial hypertension, and untreated sepsis. Psychosocial contraindications include

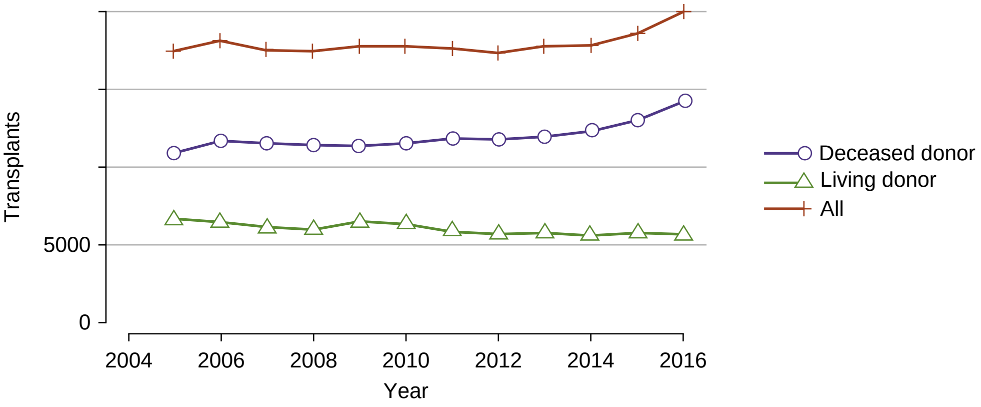

Fig. 60.4 U.S. kidney transplantation trends, 2004–2016. (From Hart A, Smith JM, Skeans MA, et al. OPTN/SRTR 2016 Annual Data Report: Kidney. *Am J Transplant.* 2018;Suppl 1:18–113.)

alcohol or recreational drug use, and the lack of social support, which might preclude compliance with immunosuppression regimens, follow-up care, or both. Age alone is generally not a contraindication unless associated with a low actuarial life expectancy (median survival), such as in the case of liver transplant, under 5 years posttransplant. More often a combination of age and comorbidities will exclude transplant in the older patient.

The success of organ transplantation relies heavily on a highly specialized team approach that includes the organ procurement organization, transplant coordinators, nurses, physicians, and allied healthcare providers. With the exception of kidney transplantation, most abdominal organ transplants are performed at tertiary medical centers with extensive resources available to support the program. Many of these centers have specialized anesthesia teams, particularly for liver and multivisceral transplantation.

This chapter reviews the anesthetic considerations for kidney, liver, pancreas, and intestinal transplantation in adults. The overall care of pediatric patients is described elsewhere in this text, as is the management of heart and lung transplantation.

Kidney Transplantation

Early attempts at human kidney transplantation date to the 1930s, however long-term success was not demonstrated until the 1950s. Kidney transplantation remained an experimental treatment for renal failure with isolated cases from various centers demonstrating varying success until breakthroughs in tissue typing and immunosuppression led to improved graft survival.

Today, kidney transplantation is the most common organ transplant surgery performed. Kidney transplant rates continue to rise on an international scale with growth of kidney transplant programs throughout Europe, North America, and Asia, as well as in many developing countries. Worldwide, there are substantial differences in the distribution of living versus cadaveric donor organs determined by cultural barriers to deceased donation or lack of organ procurement facilities. Many countries in Africa and Asia rely exclusively on living donation, whereas some countries in Europe perform mainly cadaveric renal transplants.[4] However, many developing countries have implemented national deceased donor kidney transplant distribution systems that have steadily increased access to transplantation.[5,6] Despite this effort, obstacles remain for renal transplant programs in many developing countries including patient access to care, costs, infrastructure, and cultural barriers.[7] Regardless of location, the lack of donors in the setting of increasing rates of end-stage renal disease (ESRD) affects all countries equally.

The demographics of kidney transplant patients in the United States have changed over the past 2 decades for many reasons, including an aging population and higher prevalence of diabetes and hypertension. Diabetes and hypertension are the two most common etiologies of ESRD in adults in the United States. Although it is not known how many patients with chronic kidney disease (CKD) progress to ESRD, the prevalence of ESRD in the United States has continued to increase. There were 703,243 documented cases of ESRD in the United States at the end of 2015, a 3.4% increase from the prior year.[8] ESRD also continued to increase on an international level; all countries that reported data in 2015 showed increased prevalence from the year before.[9] Although the prevalence of ESRD in the United States has continued to increase, this observation may reflect longer survival of patients with the diagnosis of ESRD. Encouragingly, 30% of all ESRD cases reported in the United States at the end of 2015 had a functioning kidney transplant.[8]

In the United States, the national kidney transplant waitlist steadily increased up to the year 2014, reflecting an increased incidence of CKD in older populations due to hypertension and diabetes. However, in 2016, the waitlist for kidney transplant decreased for the second year in a row; 30,869 patients were added to the United States waitlist while 33,291 patients were removed.[10] In concordance, the total number of kidney transplants performed in the United States increased in 2016 for the second year in a row as well; a total of 19,060 were performed. This increase in kidney transplant activity was directly due to an increase in deceased donor transplants, as living donor transplants remained stable (Fig. 60.4).[10] A new kidney allocation system implemented in the United States at the end of 2014 was likely responsible for this observed increase in deceased donor kidney transplants. This system was designed to

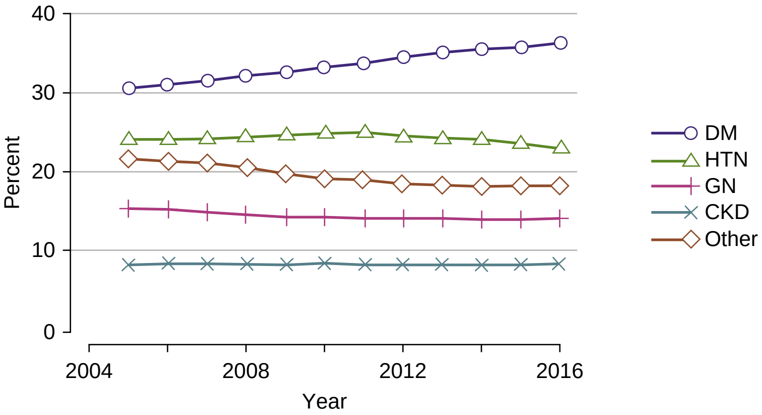

Fig. 60.5 Distribution of adults awaiting kidney transplant in U.S. 2004–2016 by diagnosis. *CKD,* Cystic kidney disease; *DM,* diabetes; *GN,* glomerulonephritis; *HTN,* hypertension. (From Hart A, Smith JM, Skeans MA, et al. OPTN/SRTR 2015 Annual Data Report: Kidney. *Am J Transplant*. 2018;Suppl 1:18–113.)

improve transplant equity by increasing access to deceased donor kidney transplants for a number of candidate subgroups including racial/ethnic minorities, B blood type candidates, highly sensitized candidates, and those with a history of prolonged dialysis prior to listing.[11] Analysis of the results of this new allocation policy demonstrated a 7% increase in kidney transplants performed in the first 18 months after implementation with observed increases in transplant rates in many of the prioritized subgroups.[12] Despite these recent successes, more patients were removed from the transplant list in 2016 than in previous years because of being too ill for transplant.[10] This trend reflects a kidney transplant population that is older and more likely to suffer from chronic diseases, which also has significant implications regarding perioperative risk during kidney transplant. Nevertheless, continued improvements in both short- and long-term living and deceased donor graft outcomes were reported in 2016.[10] One-year deceased donor graft survival rates remain over 90% in the United States, Europe, Canada, and Australia/New Zealand. Five-year deceased donor survival rates are slightly better in Europe, Canada, and Australia/New Zealand compared to the United States for reasons that are not completely defined.[13]

Despite an observed graft survival advantage for living kidney transplants over deceased donor transplants, the rates of living donor transplants have remained static over the past 10 years in the United States at approximately 5000 per year for reasons that are not fully understood.[10,13] Paired donation, consisting of two incompatible donor-recipient pairs exchanging kidneys to create two compatible pairs, is a strategy to increase access to living donors. Paired donation has increased in both the United States and internationally. With the development of donor chain transplants and establishment of organized allocation systems for paired donation, these techniques are expected to increase the future rate of living donor kidney transplants.[14]

INDICATIONS FOR KIDNEY TRANSPLANTATION

Kidney transplantation is indicated in patients with ESRD caused by any one of a variety of underlying conditions. Glomerular disease, congenital diseases, and polycystic kidney disease are common indications in younger patients. Nephropathies associated with hypertension and diabetes are the most common indications for kidney transplantation in the United States. Diabetes is the leading cause of ESRD in the United States, representing 36% of all waitlisted candidates in 2016 (Fig. 60.5).[10] Renal graft failure is an increasingly common indication for transplantation as well. In 2015, 16% of all waitlisted candidates in the United States were awaiting retransplantation and higher percentages have been reported in other countries.[15,16]

PATHOPHYSIOLOGY OF END-STAGE RENAL DISEASE

ESRD refers to the final progression of CKD, when renal function is irreversibly impaired and the development of uremia is imminent. Essential functions of the kidney include regulation of the ionic composition of the plasma, maintenance of fluid volumes, elimination of nitrogenous wastes and drugs, synthesis of erythropoietin, and adjustment of plasma pH. Significant declines in glomerular filtration rate (GFR) and urine production occur when these critical functions are damaged, resulting in the clinical manifestations of uremia. After the development of ESRD, renal replacement therapy is required. ESRD has an effect on nearly every organ system, and it has a major impact on patient mortality despite chronic therapy including hemodialysis.

ESRD results in abnormalities of fluid balance and electrolytes. With the onset of uremia and oliguria, expansion of the extracellular fluid volume ensues, presenting with edema, hypertension, and signs and symptoms of volume overload. Disorders of sodium, calcium, magnesium, and phosphate can result in chronic changes in bone metabolism, hyperparathyroidism, and vascular calcifications. The development of hyperkalemia, with its effects on the myocardium, is the most critical electrolyte abnormality. Failure of the renal elimination of organic acids results in the development of an anion-gap metabolic acidosis.

ESRD has a significant effect on the cardiovascular system. Cardiovascular disease is the most common cause of morbidity and mortality in patients with ESRD, accounting for 35% to 40% of all deaths in patients receiving hemodialysis.[17] As GFR decreases, the risk of cardiac mortality increases.[18] ESRD increases the development of atherosclerosis and is a major risk factor for the development of ischemic vascular disease, which can affect the coronary, cerebrovascular, and peripheral vascular systems. The likelihood of CAD, which can present as angina, myocardial infarction, arrhythmia, or sudden cardiac death, may be even greater in patients with hypertension and diabetes. Hypertension may be the etiology of ESRD in nearly 30% of patients, or conversely, hypertension may result from hyperreninemia, hypervolemia, and renal vasculature changes associated with ESRD. Concentric left ventricular hypertrophy and diastolic dysfunction occur in the early stages of CKD, and are the two most common echocardiographic abnormalities in patients with ESRD.[19] Patients with ESRD are at particular risk for diastolic congestive heart failure, especially in the setting of excessive intravascular volume. Heart failure owing to dilated cardiomyopathy with decreased systolic function can occur in patients with ESRD as well. The cardiorenal syndrome is defined by an interconnection between the renal and cardiac systems, where the decline of one organ influences the decline of the other. There is evidence that correction of renal function by renal transplantation can improve systolic dysfunction and reverse left ventricular dilation and hypertrophy.[20,21] A variety of arrhythmias can occur in ESRD because of progression of cardiac disease, myocardial ischemia, or electrolyte disturbances. Atrial fibrillation occurs in up to 27% of patients on hemodialysis and is associated with an increased risk of stroke, heart failure, and hemodynamic disturbance. Stroke is of significant concern in ESRD patients with atrial fibrillation, as patients with ESRD have nearly a 50% increased risk of stroke compared to the general population.[22] Clinical dilemmas are common regarding anticoagulation in patients with atrial fibrillation and ESRD. Pericardial disease is common in patients with uremia, manifesting as pericarditis or pericardial effusion.

Characteristic hematologic and hemostatic abnormalities occur with ESRD. Normochromic, normocytic anemia secondary to lack of erythropoietin is common and may be exacerbated by iron deficiency, chronic inflammation, and bone marrow fibrosis. Anemia decreases quality of life in ESRD and is associated with adverse cardiac outcomes. Erythropoiesis-stimulating drugs and iron are commonly prescribed for the treatment of uremic anemia, and hemoglobin levels of 11 to 12 gm/dL are typically achieved.[23] ESRD is associated with abnormal hemostasis because of a broad spectrum of platelet function abnormalities including decreases in platelet activity, aggregation, and adhesiveness. Production of von Willebrand factor and factor VIII is decreased. Historically, renal failure patients were considered to be at an increased risk for bleeding. However, ESRD is also associated with a hypercoagulable state owing to a variety of complex hemostatic changes including increased fibrinogen levels, reduced antithrombin levels, acquired thrombophilic factors, and endothelial alterations. Clinically, the risk of venous thromboembolism appears to increase as renal function decreases; manifestations may include deep venous thrombosis/pulmonary embolism and thrombosis of arteriovenous fistulas and vascular access catheters.[24] Many of the hematologic changes of hypercoagulability have been shown to resolve in patients with ESRD after kidney transplantation.[25]

Gastrointestinal signs and symptoms of ESRD include nausea, vomiting, and abdominal pain. Patients with ESRD may have delayed gastric emptying, regardless of the timing of their last oral intake. Dyspepsia occurs in 50% to 70% of patients on hemodialysis; ESRD patients with symptomatic dyspepsia have been shown to have particularly prolonged gastric emptying times.[26] The presence of diabetes and obesity may further impair gastric emptying.

Central nervous system and neuromuscular abnormalities can occur in ESRD secondary to retained nitrogenous molecules. These abnormalities range from mild changes in memory or attention to signs and symptoms of neuromuscular irritability. Severe neurologic manifestations of uremia with asterixis, seizures, and decreased mental status are rare with regular dialysis. Peripheral neuropathy is the most common neurologic manifestation of ESRD and is documented in up to 90% of dialysis patients. Autonomic dysfunction is also common, documented in up to 50% of dialysis patients. Autonomic neuropathy is implicated in ESRD patients with orthostatic hypotension, cardiac arrhythmias, and gastric dysmotility. Kidney transplantation is the most effective treatment for the neurologic manifestations of ESRD.[27]

ANESTHESIA FOR KIDNEY TRANSPLANTATION: PREOPERATIVE EVALUATION

Before kidney transplantation, patients typically undergo a prolonged pretransplant evaluation by a multidisciplinary transplant committee to determine their fitness for transplantation and to assess for the likelihood of long-term survival following transplantation. In general, the preoperative evaluation of patients for kidney transplant should focus on the multiorgan manifestations of ESRD, with the goals of risk stratification and optimization of the medical status of the patient before transplant. Cadaveric kidney transplantation is an urgent procedure, because harvested organs tolerate a finite duration of cold ischemia of approximately 24 hours. Living donor kidney transplants are scheduled well in advance, allowing for a thorough preoperative assessment before surgery.

As discussed previously, the current demographic of kidney transplant patients has a frequent association with cardiac disease, which has a major effect on posttransplant outcome. As a result, preoperative cardiac evaluation is of critical importance in this patient group. Compared with the routine preoperative evaluation of surgery patients without cardiac disease, the renal transplant patient should be assessed to consider both short- and long-term cardiac outcomes. The goal of the preoperative cardiac evaluation is ultimately to decrease the morbidity and mortality associated with cardiovascular disease in kidney transplant candidates. Although decisions regarding candidacy in high-risk patients are usually made well before surgery, the anesthesiologist should be involved in the routine cardiac risk assessment of the kidney transplant patient before surgery. The major focus of the preoperative cardiovascular assessment in kidney transplant patients is to identify occult ischemic heart disease.

The 2014 American College of Cardiology/American Heart Association (ACC/AHA) Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery recommends a preoperative algorithm designed to assist in the risk stratification of surgical patients. The stepwise algorithm includes identification of known CAD or CAD risk factors, estimation of the perioperative risk for major adverse cardiac events based on combined clinical and surgical risk factors, and determination of functional capacity. The decision to proceed with surgery or to undergo further noninvasive ischemia testing is contingent on functional capacity, scored by metabolic equivalent tasks (METS). No further testing is recommended when functional status is considered moderate or good (more than 4-10 METS) or excellent (more than 10 METS). If functional status is less than 4 METS or cannot be assessed, further ischemia testing may be considered.[28] The utility of published guidelines to detect patients with ischemic heart disease has been called into question in the kidney transplant population and, in contrast to the 2014 more general guidelines, in 2012, the AHA and the American College of Cardiology Foundation issued a scientific statement stating that the cardiac evaluation and management among kidney and liver transplantation patients should form the basis of the long-term evaluation of the transplant patient.[29] Silent myocardial ischemia may occur more frequently in patients with ESRD than in the general population, making the detection of unstable coronary syndromes more difficult. One study reported that chest pain presenting at the time of acute myocardial infarction was less common in patients with ESRD requiring dialysis compared with patients not using dialysis (44% vs. 68%).[30] Decreased functional status might not be a specific or sensitive indicator of cardiovascular risk in kidney transplant candidates, and many ESRD patients are unable to exercise secondary to deconditioning. One study of kidney transplant candidates examined the effectiveness of various guidelines to detect asymptomatic CAD. The authors determined that if the 2014 ACC/AHA guidelines had been strictly applied to this group of patients, only a small proportion of the candidates with documented myocardial ischemia on noninvasive testing would have been detected.[31] Finally, renal insufficiency is itself a CAD risk factor. The unique characteristics of ESRD patients, along with discrepancies among published guidelines, has called into question the applicability of available recommendations regarding cardiac testing in the kidney transplant population.[29]

Noninvasive testing methods for CAD have been well studied in the kidney transplant population, although most investigations consisted of small study populations. In studies that compared either dobutamine stress echocardiography (DSE) or myocardial perfusion imaging with angiography in patients with renal failure, both methods demonstrated decreased accuracy compared to their accuracy in nonrenal failure patients.[29,32] The response to coronary vasodilators appears to be decreased in ESRD patients with diabetes; this may contribute to false negative myocardial perfusion testing results.[33] Chronotropic incompetence may diminish the maximum heart rate response to dobutamine in patients with ESRD and left ventricular hypertrophy may limit detection of reversible wall motion abnormalities during echocardiographic stress testing.[34] Although noninvasive testing appears to be less reliable in kidney transplant patients compared to the general population, ischemia detected on noninvasive testing correlates with adverse cardiac events and mortality in patients with ESRD and in kidney transplant patients.[35,36] One meta-analysis that analyzed studies using either DSE or myocardial perfusion studies in patients with ESRD demonstrated that patients with inducible ischemia or fixed defects had a significantly increased risk of cardiac death compared with patients with normal tests.[37]

Although many guidelines and consensus-based recommendations regarding preoperative cardiac risk assessment in kidney transplant candidates have been published, there is no validated standardized approach.[29,38] A stepwise process including a comprehensive cardiovascular history and evaluation of signs and symptoms of advanced cardiac disease, assessment of functional status, and identification of risk factors should be reviewed.

A baseline electrocardiogram (ECG) is an appropriate initial screening test in most kidney transplant patients, especially in patients older than 40 years. ECG abnormalities associated with cardiac disease are common in patients with ESRD. A preoperative ECG should be obtained in patients with known CAD, peripheral vascular disease, and cardiac symptoms.[29] Noninvasive testing may be considered in asymptomatic patients with multiple risk factors for CAD. The most recent consensus document published in 2012 by the ACC/AHA provides recommendations for preoperative cardiac testing in kidney transplant candidates.[29] Noninvasive ischemia testing should be considered in candidates with three or more of the following risk factors: known cardiovascular disease, diabetes, dialysis for more than 1 year, age over 60 years, tobacco use, left ventricular hypertrophy, dyslipidemia, and hypertension. The authors also recommend that the decision to proceed with noninvasive testing based on the presence of the above risk factors should be made regardless of functional status in kidney transplant candidates.[29]

Preoperative assessment of left and right ventricular function by echocardiography is an appropriate test in most kidney transplant candidates.[29] The likelihood of structural cardiac abnormalities and the potential for left ventricular dysfunction in ESRD is significant, and transthoracic echocardiography provides detailed information regarding resting cardiac function and structure with minimal testing risk.

An increased prevalence of occult pulmonary hypertension, up to 40% reported in one series, occurs in patients receiving dialysis. The mechanism involves both uremia-induced pulmonary vasoconstriction and increased cardiac output secondary to an arteriovenous fistula. Pulmonary hypertension may be reversible after kidney transplantation. The identification of pulmonary hypertension is important because its presence in patients with ESRD is associated with decreased survival.[39] Right heart catheterization may be indicated in patients with evidence of significant pulmonary hypertension by echocardiography.

Patients with cardiac conditions may remain on transplant lists for many years before undergoing transplantation. During this time, cardiac disease can progress. Although routine periodic noninvasive screening in asymptomatic patients awaiting transplant is not warranted, patients with known cardiac disease should undergo regular repeat cardiac assessments although the frequency of assessments has not been defined.[29]

Cardiovascular medications should be reviewed during the preoperative evaluation in kidney transplant candidates, and the patient advised on which medications should be taken before surgery. Most patients with ESRD receive multiple medications for the chronic treatment of hypertension; however, the ideal combination of drugs is not clear. Strategies for the perioperative administration of antihypertensive blood pressure medications are important; however, the urgency of deceased-donor kidney transplantation often allows only the immediate preoperative administration of antihypertensive medications. The risks and benefits of initiating or maintaining perioperative medical therapy in surgical patients have been extensively reviewed in the most recent ACC/AHA guideline; β-blockers, statins, α-2 agonists, calcium channel blockers, and angiotensin-converting enzyme inhibitors were included.[28] There is limited information regarding perioperative antihypertensive therapy and its impact on survival in kidney transplant patients. In general, it is reasonable to apply current ACC/AHA recommendations regarding perioperative antihypertensive therapy in kidney transplant candidates.

As mentioned previously, there is an increasingly high prevalence of diabetes in the kidney transplant population. Perioperative hyperglycemia is associated with adverse outcomes in both diabetic and nondiabetic populations.[40] Perioperative glycemic therapy should be initiated in patients with diabetes who are undergoing kidney transplant, yet a benefit from strict blood glucose control in the kidney transplant population has not been demonstrated. Studies demonstrating the risks of hypoglycemic episodes in protocols employing “tight” glucose control in surgical and intensive care unit (ICU) patients suggest that conventional glycemic targets may be safer during the perioperative period.[41,42] Most medical society organizational guidelines recommend targeting blood glucose levels between 110 to 160 mg/dL and initiating insulin therapy for blood glucose levels over 180 mg/dL during the perioperative period.[40]

Day of Surgery

Prior to surgery, patients receiving hemodialysis should be maintained on their regular dialysis schedules. If possible, dialysis should be performed immediately prior to surgery. Preoperative laboratory assessment of electrolytes, complete blood count, and platelet count is necessary in all kidney transplant patients on the day of surgery. Documentation of an increased potassium level, especially with ECG changes consistent with hyperkalemia, should prompt consideration for the delay of surgery and for immediate dialysis to correct potassium levels. Preoperative vital signs should be closely assessed, especially heart rate and arterial blood pressure trends in hospitalized patients. Preoperative intravascular volume status should be assessed. Comparing the patient’s current weight to their known euvolemic weight, or “dry weight,” may be helpful. Orthostatic assessments and the presence of resting hypotension and increased heart rate may identify significant hypovolemia. Patients who have preoperative body weights heavier than their euvolemic weight may have an excessive intravascular volume and may be at risk for congestive heart failure during the perioperative period. A thorough cardiopulmonary examination is indicated in all patients, and findings of significant excessive intravascular volume may be an indication for immediate preoperative dialysis. On the day of surgery blood glucose levels should be measured; insulin therapy may be initiated in patients before surgery for significant hyperglycemia, with appropriate serial blood glucose measurements during the perioperative period. As in all types of surgery, orally administered antihyperglycemic medications should be withheld in patients with non–insulin-dependent diabetes. A type and screen or crossmatch for packed red blood cells should be obtained. Although major blood loss during routine kidney transplantation is not common, the surgery involves major vascular structures and catastrophic rapid bleeding can occur. Finally, in patients with known cardiac disease or in those with changes in cardiac symptoms, bedside ultrasound examination of cardiac structures may be indicated, particularly to assess for changes in ventricular function, valvular pathology, or pericardial disease.

ANESTHESIA FOR KIDNEY TRANSPLANT: INTRAOPERATIVE MANAGEMENT

General anesthesia with endotracheal intubation is the preferred anesthetic method for kidney transplantation in most institutions. The goals of anesthesia are to facilitate an adequate depth of anesthesia while maintaining hemodynamic stability and to provide appropriate muscle relaxation to facilitate surgical conditions. As mentioned previously, patients with ESRD are considered at risk for aspiration of gastric contents secondary to the presence of uremic gastropathy and other conditions, such as obesity and diabetes. An oral nonparticulate antacid and intravenous administration of an H-2 blocker may be considered before induction of anesthesia. A rapid-sequence induction of anesthesia is the preferred method of induction for general anesthesia. Succinylcholine can be used safely in standard doses in patients with ESRD when potassium levels are within normal limits (usually < 5.5 mEq/L). Potassium transiently increases 0.5 to 1.0 mEq/L for 10 to 15 minutes before returning to baseline levels in patients with ESRD and those with normal renal function.[43] A modified rapid-sequence induction using rocuronium 0.8 to 1.2 mg/kg intravenously may be a substitute for succinylcholine when hyperkalemia or other contraindications to succinylcholine exist. Rocuronium should be used in ESRD with caution as the duration of action is prolonged. A meta-analysis of 26 studies that compared the intubating conditions produced by succinylcholine and rocuronium found that intubation conditions were clinically similar when propofol was used as the induction anesthetic.[44] The hemodynamic response to laryngoscopy may be accelerated in patients with ESRD with underlying chronic hypertension. Tachycardia and hypertension can be attenuated with supplemental short-acting agents or opioids titrated to effect. Following the stress of tracheal intubation, kidney transplant patients may develop hypotension before surgical incision, especially in patients who have been rendered hypovolemic from recent dialysis or in patients receiving renin-angiotensin blocking drugs.

Intraoperative monitoring may be limited to standard noninvasive monitors in younger, healthier transplant recipients and in select living donor recipients. Intraarterial blood pressure monitoring can be beneficial, especially in patients with uncontrolled hypertension, CAD, or heart failure. A radial arterial catheter, if used, is placed contralateral to a preexisting arteriovenous fistula and the femoral artery is typically avoided. Femoral access on the side selected for implantation is contraindicated due to the risk of hematoma or thrombosis adversely affecting the implanted graft. It is important to assess the risk versus benefit of arterial access in ESRD patients, as upper extremity arterial lines may jeopardize future arteriovenous access for dialysis. Pulmonary artery (PA) catheter or transesophageal echocardiographic monitoring may be considered in patients with advanced CAD, left or right ventricular dysfunction, and pulmonary hypertension but is rarely indicated otherwise. Central venous pressure monitoring may be employed in some centers; however, central venous pressure is not a reliable monitor of fluid status or responsiveness.[45] The insertion of a central line provides reliable venous access for intravascular fluid resuscitation and transfusion, easy blood sampling, and access for administration of immunosuppression drugs and vasoactive infusions. In patients without a preexisting arteriovenous fistula or dialysis catheter, a central line allows urgent postoperative dialysis, if required. Many centers find central line insertion unnecessary; the risks and benefits of central line placement should be considered. Large-bore venous access is necessary for appropriate intravascular volume administration. Intravenous access can be challenging in some kidney transplant patients, as intravenous sites may be limited by the presence of an upper extremity arteriovenous fistula. Conversely, central venous access may be difficult to accomplish in patients with ESRD who have undergone multiple previous central venous dialysis catheter placements, especially if central venous thrombosis has been documented.

Maintenance of anesthesia is typically performed using a combination of intravenous and inhaled anesthetics. Volatile inhaled anesthetics are titrated to the level of surgical stimulation. Desflurane and isoflurane are not associated with nephrotoxicity. Although sevoflurane has potential nephrotoxic effects from the metabolites compound A and fluoride ion, detrimental effects on renal function have not been demonstrated in patients with renal insufficiency.[46,47] Although large prospective studies are lacking in kidney transplant patients, the use of sevoflurane during kidney transplantation appears to be a reasonable anesthetic choice.

Analgesia during the intraoperative period can be provided with the synthetic opioids fentanyl, sufentanil, alfentanil, and remifentanil because their pharmacokinetics and pharmacodynamics are not affected by renal insufficiency. Morphine, oxycodone, and meperidine should be used sparingly in patients with renal failure because these drugs have active metabolites that accumulate in these patients.

Appropriate neuromuscular blockade during kidney transplantation may facilitate optimal surgical conditions; however, recovery from neuromuscular blockade may be variable in patients with ESRD regardless of the drug used.[48] Vecuronium and rocuronium have prolonged durations of action in renal failure patients, because their clearances rely both on renal and hepatic metabolism. Cisatracurium is likely the muscle relaxant of choice in patients with ESRD, because it undergoes organ-independent clearance. Pancuronium is primarily eliminated by the kidneys, and probably should be avoided in patients with renal failure. For patients with ESRD who are undergoing kidney transplantation, judicious use of neuromuscular blocking drugs is a necessity. Titration to surgical conditions and close monitoring of the level of neuromuscular blockade are crucial.

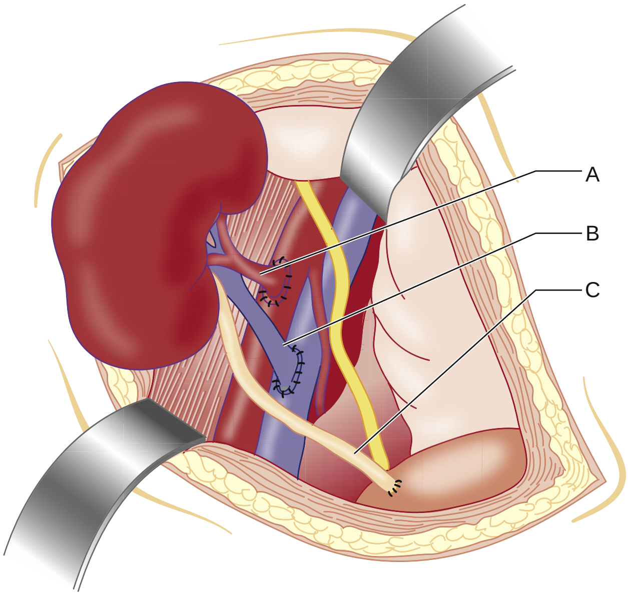

Fig. 60.6 Renal transplantation. *A,* Renal artery anastomosis performed end-to-side to the external iliac artery. *B,* Renal vein anastomosis performed end-to-side to the external iliac vein. *C,* Ureteral anastomosis to the bladder mucosa. (From Hardy JD. *Hardy's Textbook of Surgery*. 2nd ed. Philadelphia: JB Lippincott; 1988.)

The surgical procedure involves placement of the renal allograft in the left or right extraperitoneal fossa, although the right side is usually preferred (Fig. 60.6). A vertical curvilinear incision 20 to 25 cm long is typically made, extending from the pubis symphysis to above the anterior superior iliac spine. The abdominal musculature is divided, and the peritoneum is entered and retracted. During the initial incision and dissection, surgical stimulation is increased and hemodynamic responses may be exaggerated in some patients. Adequate analgesia, depth of anesthesia, and muscle relaxation should be appropriately titrated to effect. The external iliac vein and artery are identified and mobilized. Occasionally, different vascular structures are chosen for the renal anastomoses. Heparin may be administered before clamping of the vessels. The external iliac vein is clamped first, and the renal vein anastomosis is performed. Next, the external iliac artery is clamped and the renal artery anastomosis is performed. During the anastomoses of the renal vessels, expansion of intravascular volume with balanced salt solutions should be initiated. Furosemide and mannitol are administered before reperfusion to stimulate diuresis. Mannitol, along with adequate intravascular volume resuscitation, decreases the likelihood of acute tubular necrosis in renal transplantation.[49] Adequate intravascular volume expansion with crystalloid or colloids increases renal blood flow, which improves immediate graft function.[48] At the time of removal of the vascular clamps, additional intravascular volume expansion may be required to stabilize hemodynamics. On rare occasions, removal of vascular clamps may be associated with acute bleeding requiring further resuscitation and transfusion. Hypotension following reperfusion will result in hypoperfusion of the graft. Hypotension may precipitate renal injury owing to ischemia and can contribute to vascular thrombosis of the graft. Appropriate decreases in the depth of volatile anesthetic and volume expansion will maintain adequate renal perfusion pressures in most patients. In the event of hypotension, adrenergic vasopressors are typically avoided because of renal vasoconstrictive effects. Hypotension unresponsive to volume expansion may require interventions to increase cardiac output, especially in high-risk patients. Invasive hemodynamic monitoring is invaluable in this situation. Inotropic agents may be necessary to maintain renal perfusion pressure; there is no consensus regarding which agent is preferred in kidney transplant patients. After completion of the vascular anastomoses, the donor graft ureter is implanted into the recipient bladder. The bladder is filled with antibiotic saline irrigation solution by way of a three-way Foley catheter, allowing for implantation of the donor ureter. A temporary ureteral stent may be placed as well. After completion of the bladder anastomosis, the wound is closed in layers. Neuromuscular blockade should be maintained until the fascial layer has been closed to prevent straining or coughing that could potentially disrupt the graft position or vascular connections. During emergence, exaggerated hemodynamic responses are common, especially in patients with poorly controlled hypertension. Appropriate titration of short-acting drugs to attenuate these responses upon emergence is helpful, especially in patients at risk for CAD. Careful neuromuscular blockade monitoring and appropriate administration of reversal agents are central to avoiding postoperative pulmonary complications. Sugammadex, a binding agent specific for rocuronium, forms an inactive complex that is primarily cleared by the kidneys. Clearance of this complex is reduced in ESRD patients, although removal of this complex using dialysis has been demonstrated.[50] Sugammadex has been shown to be clinically effective in ESRD patients, however its safety has not yet been demonstrated in kidney transplant populations.[51] ESRD patients may demonstrate delayed emergence from anesthesia and have exaggerated responses to opioids and sedative-hypnotics. Extubation of the trachea should occur after the patient demonstrates the ability to protect the airway, because kidney transplant patients are still considered a risk for aspiration of gastric contents at the completion of surgery.

ANESTHESIA FOR KIDNEY TRANSPLANT: POSTOPERATIVE MANAGEMENT

After extubation of the trachea, the kidney transplant recipient requires careful monitoring in the postanesthesia care unit. Close monitoring of urine output in the initial postoperative period is important. Acute decreases in urine output should initiate a rapid evaluation of the etiology and appropriate treatment. A prerenal etiology should be treated with aggressive intravascular volume resuscitation. In some patients, additional invasive hemodynamic monitoring may be required. Postrenal etiologies owing to technical problems with the ureteral anastomosis may require early surgical re-exploration. Postoperative surgical complications include vascular thromboses, wound hematomas, and infection. Nonsurgical cardiovascular, pulmonary, and gastrointestinal postoperative complications are not unusual after kidney transplant; one institution reported a 90-day severe postoperative complication rate of 15%.[52] High-risk patients with advanced cardiac and pulmonary disease may require further postoperative monitoring in the intensive care setting. In general, postoperative intensive care admissions for kidney transplant recipients are much less common than for liver and kidney-pancreas transplant recipients. One single-center study found a 6% rate of ICU admission following kidney transplant. The mortality rate in kidney transplant patients that required intensive care admission was higher than in nontransplant ICU patients.[53]

Postoperative pain control is usually provided with synthetic opioid analgesics without active metabolites. Pain after kidney transplant is highly variable; in some patients, pain may be severe and challenging to treat effectively. Renal failure alters the pharmacology of most opioid medications; dose reductions are generally required in renal failure patients. In addition, chronic underlying pain conditions and opioid dependence may impact postoperative pain following kidney transplant; chronic pain conditions occur in 40% to 60% of dialysis patients.[54] Patient-controlled opioid analgesia is commonly initiated in the postanesthesia care unit and continued for 24 to 48 hours. Regional anesthesia for kidney transplantation is controversial. One report demonstrated effective postoperative analgesia in kidney transplant recipients with epidural analgesia, however concerns for uremic coagulopathy and hypotension have limited its widespread use in kidney transplant patients.[55] Although transversus abdominis plane block has been advocated for postoperative analgesia in kidney transplant patients, results from randomized controlled trials have been inconsistent.[56-58]

ORGAN MATCHING AND ALLOCATION

Organ matching for kidney transplantation involves several steps to determine compatibility between donor and recipient. Initially, matching of the major ABO blood group is determined for all donors and recipients. Before the transplant surgery, a crossmatch is performed by mixing recipient blood with donor blood cells. This crossmatch is performed to identify any recipient antibodies that are reactive against donor antigens. Histocompatibility matching is an important part of the matching process, in which the human lymphocyte antigen (HLA) profile of the recipient is determined and compared with the HLA profile of the donor. Organ rejection by the recipient's immune system is mediated by the recognition of mismatched (non-self) HLAs located on the surface of donor cells. Many standard HLAs are compared between potential donors and recipients before transplantation. In general, graft survival rates are worse with HLA-mismatched grafts. Although better immunosuppression has improved the overall survival rates for kidney transplants during the past 3 decades, the graft loss rate for HLA-mismatched kidneys has remained higher than HLA-matched grafts.[59] For all potential recipients awaiting a deceased donor, their HLA profile is compared to the donor profile, and an appropriate donor-recipient pairing is made based on the best match. For living donors, HLA matching is performed well in advance of the surgery. The U.S. kidney allocation system implemented in 2014 prioritizes deceased donor transplantation for highly sensitized candidates, a group of candidates that have previously endured prolonged waitlist times before receiving organ offers. One-year analysis of the new kidney allocation system demonstrated a fourfold increase in the transplant rate for highly sensitized candidates with an overall 6-month graft survival rate that matched the years prior.[11]

ANESTHESIA FOR PATIENTS AFTER KIDNEY TRANSPLANTATION

After successful kidney transplantation, most patients are classified as having National Kidney Foundation stage 2 or 3 CKD with usual GFRs more than 30 mL/min. GFR typically deteriorates by 1.4 to 2.4 mL/min/year in renal transplant recipients.[60] Posttransplant mortality increases as renal graft function deteriorates. Renal function is followed closely within the first few years after transplant to assess for rejection, which is identified by worsening organ function. In post–kidney transplant patients undergoing nontransplant surgery, renal function should be assessed before surgery. Most patients will be under the care of a nephrologist within the first years of a kidney transplant; assessment of the patient's medical records or renal function tests should be obtained preoperatively. Rejection should be ruled out before nontransplant surgery, as surgery during an episode of rejection can increase morbidity.[61]

Although successful kidney transplantation decreases overall cardiovascular risk in ESRD patients, cardiovascular disease is more prevalent in kidney transplant recipients compared to the general population and remains the most common cause of death in kidney transplant patients.[62] As described previously, cardiovascular disease is involved in the pathogenesis of renal failure and is a consequence of kidney disease as well. Ischemic heart disease, cerebrovascular disease, and peripheral vascular disease significantly affect the survival of kidney transplant patients. Progression of preexisting CAD can occur in the posttransplant patient, as immunosuppression contributes to the development of de novo hyperlipidemia, hypertension, and diabetes. The incidences of hypertension (92%), hyperlipidemia (66%), diabetes (41%), and obesity (38%) are increased in kidney transplant recipients.[63] Known CAD in kidney transplant recipients has been documented in 10 centers worldwide and 20% of selected populations, but the prevalence of CAD likely increases in the years following transplant.[63,64] Because long-term studies on cardiac outcomes following nontransplant surgery in kidney transplant recipients are lacking, there are no specific recommendations for cardiovascular evaluations in kidney transplant recipients. For previous kidney transplant patients undergoing nontransplant surgery, the ACC/AHA guideline for perioperative cardiovascular evaluation for noncardiac surgery should be used to guide preoperative cardiovascular testing.[28]

Other disease processes related to kidney disease and immunosuppression should be sought. Kidney transplant patients are at increased risk for posttransplant malignancies, anemia, and osteodystrophy. Infection is a constant concern in kidney transplant recipients, because they are at risk for both opportunistic and community-acquired infections. Cytomegalovirus (CMV) infection is the most common infection in kidney transplant patients, and it is rarely acquired by transfusion. CMV-negative blood should be used when transfusions are required in patients who are CMV negative.

Anesthesia for nontransplant surgery can be accomplished safely with general, regional, and local sedation techniques. Most anesthetic drugs are safe in posttransplant patients, assuming the presence of adequate hepatic and renal function.[61] Although preoperative creatinine may be near normal in kidney transplant recipients, GFR in these patients is usually reduced, resulting in prolongation of the activity of drugs cleared by the kidneys. Obviously, drugs that cause nephrotoxicity should be avoided.

Pancreas Transplantation

Surgical treatment for diabetes includes pancreas transplant alone (PTA) and, in patients with diabetes and ESRD, pancreas after kidney transplant (PAK) and simultaneous pancreas-kidney transplant (SPK). Usually, a whole pancreas is transplanted from deceased donors. Less commonly, the distal pancreas is transplanted from a living donor. Islet cell transplant from a cadaveric donor is a new, nonsurgical option offering less effective glycemic control. This involves infusion of β cells into the portal vein, typically done under sedation in an imaging unit.[65]

The first successful pancreas transplant was performed in 1966. Due to improvements in surgical technique, donor-recipient matching, graft surveillance, and immunosuppression, pancreas transplant graft survival has improved and now matches graft survival rates of kidney and liver transplant.[66] In 2016, the United States reported rates of 90-day graft survival were 92% for PAK, 91% for PTA, and 92% for SPK, all improved from 10 years prior.[67] Worldwide, pancreas transplant rates increased during the 1990s as outcomes improved. Despite these improvements, the rates of pancreas transplants in the United States peaked in the early 2000s and declined steadily thereafter.[66] However, in 2016 there was a total of 1013 pancreas transplants in the United States, the majority SPKs. This represented a 7% increase in total pancreas transplants from the year prior, the first yearly increase in more than 10 years. This increase was likely a result of changes made to the U.S. pancreas allocation system that were implemented in 2014.[67] These changes included creation of a distinct SPK waitlist separate from the kidney waitlist, allowing the pancreas candidate access to the kidney from the same pancreas donor. Additionally, all pancreas transplant candidates are placed on a single waitlist and given equal priority to pancreas donors, regardless of the type of pancreas transplant they are to receive.[66] Despite this increase in total transplants, the U.S. pancreas transplant waitlist continues to increase with 957 new candidates added in 2016.[67]

INDICATIONS FOR PANCREAS AND KIDNEY-PANCREAS TRANSPLANTATION

Pancreas transplantation provides patients with insulin-dependent diabetes mellitus a permanent source of endogenous insulin, thus restoring normoglycemia. SPK and PAK transplants are indicated in patients with diabetes and ESRD who are deemed appropriate candidates for kidney transplantation or who have already undergone kidney transplantation. PTA is indicated in patients with diabetes without indications for kidney transplantation and who have a history of severe frequent metabolic complications, including hypoglycemia unawareness, or who have a history of problems maintaining insulin therapy that result in intractable diabetic complications.[65,68] Most patients who undergo pancreas transplant have type 1 diabetes mellitus. Rare indications for pancreas transplant include select cases of type 2 diabetes mellitus, chronic pancreatitis that has developed endocrine deficiency, cystic fibrosis with endocrine deficiency, and prior total pancreatectomy.

Previously pancreas transplant was reserved for younger patients, traditionally under age 40. For patients with diabetes and ESRD, older data found that SPK patients younger than 50 years had better reported survival rates than older patients.[69] Recently, pancreas transplant has been considered for candidates over age 50, corresponding with population trends toward more aging diabetic patients. Recent single-center studies have demonstrated similar results in pancreas transplant recipients over age 50 compared to younger patients.[70,71] These results suggest a future role for pancreas transplant expanded to older populations, a trend that has been observed in other solid organ transplant populations.[66] Regardless of patient age, survival benefits in SPK are likely due to long-term decrease in CAD complications.[72]

For patients with normal renal function who undergo PTA, long-term survival is the same as in patients receiving chronic insulin therapy.[73] Pancreas transplant appears to have a favorable effect on the progression of retinopathy as well. The progression of retinopathy is decreased or reversed in a significant percentage of PTA patients compared to diabetic patients treated with conventional insulin therapy.[74]

PATHOPHYSIOLOGY OF PANCREATIC INSUFFICIENCY

Type 1 diabetes mellitus occurs secondary to destruction of pancreatic islet cells resulting in a permanent functional loss of the endogenous production of insulin, necessitating life-long exogenous insulin therapy. The underlying cause of type 1 diabetes mellitus remains unknown. Type 2 diabetes mellitus results from peripheral resistance to the effects of insulin. Both diseases produce chronic increases of blood glucose concentrations resulting in the multiorgan manifestations of diabetes.

The chronic complications of diabetes that have the greatest effect on patient morbidity and survival are those that affect the cardiovascular system. CAD, cerebrovascular disease, and peripheral vascular disease occur in patients with diabetes owing to acceleration of atherosclerosis. Both macrovascular and microvascular disease occurs. Patients with diabetes develop CAD earlier, are more likely to have atypical symptoms, and have a higher mortality rate from myocardial infarction than nondiabetics.[75] Peripheral and autonomic neuropathies develop in diabetes, resulting in gastroparesis, lower extremity paresthesia, ulcerations, orthostatic hypotension, and labile heart rate and arterial blood pressure. Patients with diabetes have a high cumulative prevalence of blindness (16%), renal failure (22%), lower extremity amputation (12%), myocardial infarction (21%), and stroke (10%).[76]

Acute complications of type 1 diabetes mellitus typically involve conditions associated with severe hyperglycemia, such as diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma. Hypoglycemia is a direct result of exogenous insulin administration. Patients with type 1 diabetes are prone to large fluctuations in blood glucose levels. Hypoglycemic episodes contribute to acute morbidity and mortality in diabetic patients. Hypoglycemia unawareness in particular can have a marked impact on quality of life and is a frequent indication for pancreas transplant.

ANESTHESIA FOR PANCREAS TRANSPLANTATION: PREOPERATIVE EVALUATION

The preoperative evaluation for the patient undergoing pancreas transplantation involves an assessment of all of the potential acute and chronic complications of type 1 diabetes. Pancreas transplant centers pursue a comprehensive, multidisciplinary evaluation and selection process before listing candidates. The evaluation should address the organ systems most affected by long-standing diabetes, including the cardiovascular, renal, and neurologic systems. Assessment for the presence and severity of CAD should be undertaken in all candidates, including noninvasive ischemia testing, evaluation of ventricular function, and coronary angiography in select patients. Previously, patients considered for pancreas transplantation were younger than 50 years and had a lower risk for the cardiac and vascular sequelae of diabetes. Older patients are now considered for pancreas transplantation, but have a significantly higher risk for CAD and vascular disease.[77] Strategies to reduce cardiac complications, such as maintenance of β-adrenergic blockade and continuation of drugs that decrease blood lipid concentrations during the perioperative period, should be applied when appropriate.[28]

In most cases, pancreas transplantation involves a deceased-donor organ with a 24-hour maximum cold ischemia time; therefore, pancreas transplantation is considered an urgent procedure. Preoperative evaluation by the anesthesiologist should focus on any acute changes in the patient's medical status, especially those involving acute diabetic complications such as ketoacidosis and hypoglycemia. Blood glucose measurements should be assessed closely before surgery and recent insulin administration should be noted. Most patients will have a preoperative variable-rate intravenous infusion of insulin with maintenance glucose during a period of fasting. Evaluation of renal function in all candidates is important before surgery. Most patients with diabetes listed for pancreas transplant have ESRD as well and will undergo SPK. A full evaluation of electrolytes, including creatinine and potassium, should be obtained before surgery. Serial trends in heart rates and arterial blood pressures in hospitalized patients should be assessed, as most patients will have a history of hypertension requiring multiple medications, especially patients with renal failure. Preoperative assessment of intravascular volume status is especially important in patients with ESRD on hemodialysis. Finally, a directed physical examination focusing on the airway and cardiopulmonary system should be performed. The incidence of difficult tracheal intubations in patients with long-standing diabetes was thought to be more frequent because of anatomic changes of the upper airway; however recent data does not demonstrate this.[78,79] Nevertheless, attention to anatomic signs of a potentially difficult airway is important in patients with diabetes, especially those with cervical arthritis and significant obesity.

ANESTHESIA FOR PANCREAS TRANSPLANTATION: INTRAOPERATIVE MANAGEMENT

General anesthesia with endotracheal intubation is performed for all types of pancreas transplantation except islet cell transplant, which is usually done under sedation in an interventional radiology setting. The surgical procedure is typically prolonged, and an adequate depth of anesthesia and muscle relaxation is required for optimal surgical conditions. Diabetic patients and those with ESRD have a high likelihood of gastropathy and may have an increased risk for aspiration of gastric contents. Administration of an oral nonparticulate antacid preoperatively should be considered. A rapid-sequence induction of anesthesia is the safest approach to securing the airway. Patients with diabetes, ESRD, cardiovascular disease, and autonomic neuropathy may be prone to wide fluctuations in heart rate and arterial blood pressure during induction and intubation. Vital signs should be closely monitored and maintenance of hemodynamic stability should be a primary anesthetic goal, especially during and immediately following anesthetic induction. Invasive monitoring is standard for pancreas transplantation. Arterial monitoring allows for beat-to-beat arterial blood pressure measurements, as well as access for analysis of arterial blood gases and blood glucose monitoring. Central venous access may be indicated for central administration of vasoactive infusions and immunosuppression drugs. Large-bore venous access is essential, and a temporary dialysis catheter may be useful for both resuscitation and postoperative dialysis if preexisting dialysis access is absent.

Central venous pressure monitoring is used in some centers; however, the usefulness of this practice has been questioned, as central venous pressure might not be a reliable indicator of intravascular fluid responsiveness.[45] Arterial line placement before induction of anesthesia may be considered, especially in patients with severe hypertension or CAD. Anesthesia is typically maintained with a balanced technique using volatile anesthetics, opioids, and muscle relaxants. In patients with renal failure, medications should be chosen that are not dependent on the kidneys for elimination. All the caveats for the anesthetic management of patients undergoing kidney transplantation should be applied for patients undergoing SPK.

A midline surgical incision is made for both pancreas and kidney-pancreas transplant surgeries. Extensive retraction necessitates adequate muscle relaxation. Prolonged exposure of the abdominal viscera results in significant third-space losses; adequate volume expansion with crystalloid or colloids is often required. The pancreas graft is usually placed in the iliac fossa. The arterial vascular supply to the pancreas graft is usually provided by an anastomosis to the iliac artery. Usually the venous outflow from the pancreas is delivered to the iliac vein, which is associated with a lower rate of venous thrombosis. Alternatively, venous outflow may be directed to the native portal vein, which is the physiologically normal pattern of pancreatic venous efflux. There appears to be no significant advantage to portal venous drainage over systemic venous drainage for pancreas transplantation.[72]

Pancreatic exocrine drainage can be delivered to either the bladder or the intestine (Fig. 60.7). Although enteric pancreatic drainage is physiologically normal, this method is associated with surgical complications that can result in graft dysfunction, thrombosis, and early rejection. Exocrine drainage to the bladder allows for measurement of urinary amylase levels, which can be used to diagnose early rejection episodes before blood glucose levels are affected. Exocrine bladder drainage is associated with urologic complications and metabolic acidosis. Currently, most pancreas transplants utilize enteric drainage as there is no difference in graft or patient survival compared to bladder drainage.[80]

Prior to completion of the vascular anastomoses during pancreas transplantation, blood glucose levels should be assessed at least hourly as levels frequently fluctuate in brittle diabetic patients. Blood glucose should be maintained at less than 200 mg/dL, using intravenous insulin and dextrose infusions if necessary. Sliding scale insulin infusion protocols may be applied. Dextrose prevents the development of ketoacidosis during the early stages of the procedure. However, some centers stop insulin infusion when the pancreas comes out of ice, re-starting after reperfusion only if hyperglycemia is observed. Before unclamping of the vascular anastomoses, adequate volume resuscitation should be initiated. Adequate cardiac preload and normal arterial blood pressures should be the hemodynamic goals before unclamping.

After unclamping of the vascular connections, heavy bleeding can occur. This is typically from retroperitoneal and mesocolonic collaterals that are missed during cold dissection on the back table. Maintenance of adequate graft perfusion pressure is critical. Hypotension should be corrected rapidly, and intravascular volume status should be optimized. If hypotension occurs because of myocardial dysfunction, intracardiac pressure monitoring or transesophageal echocardiography can assist in the diagnosis and may help to guide therapy. Blood transfusions, colloids, and vasoactive medications may be required for the treatment of hypotension after reperfusion of the pancreatic graft. Therapy should also be guided by frequent arterial blood gas analyses with assessment of electrolytes and hemoglobin.

One of the most important intraoperative care points for pancreas transplantation is the management of blood glucose following pancreas reperfusion. After unclamping, the pancreas may release insulin into the circulation within several minutes. Blood glucose should be measured

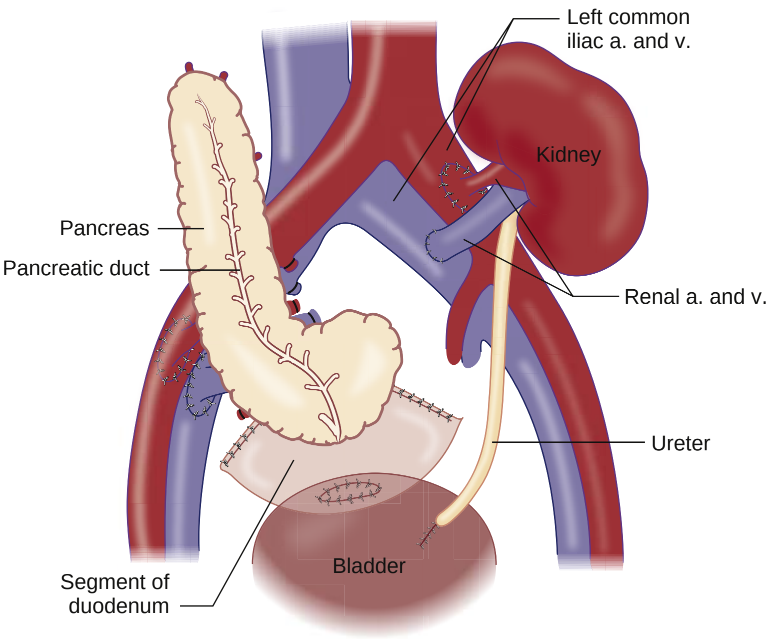

Fig. 60.7 Pancreas transplantation. Bladder drainage is through a pancreatic duodenocystostomy. A renal transplant is shown with the common iliac vessels used for vascular anastomoses. (Modified from Moody FG, ed. *Surgical Treatment of Digestive Diseases*. 2nd ed. St Louis: Mosby–Yearbook; 1990.)

approximately every 30 minutes for the remainder of the procedure. After successful transplantation, insulin requirements rapidly decline, and patients may be at risk for hypoglycemia. Delayed graft function can be identified by the presence of hyperglycemia. In this event, insulin infusion should be titrated to maintain blood glucose levels less than 200 mg/dL.[76]

ANESTHETIC MANAGEMENT OF PANCREAS TRANSPLANTATION: POSTOPERATIVE MANAGEMENT

After the completion of surgery, full reversal of neuromuscular blockade, hemodynamic stability, normothermia, and the ability of the patient to protect the airway will facilitate tracheal extubation. Pancreas transplant patients should be monitored closely in the postanesthesia care unit and ICU. Regular blood glucose measurements should be continued in the postoperative period to avoid hypoglycemia. Electrolytes, complete blood count, and analysis of arterial blood gas should be obtained immediately postoperatively, because acid-base disturbances, anemia, and electrolyte imbalances are common. Euvolemia should be maintained. Depending on the patient's age and underlying risk for CAD, serial troponins and ECG may be assessed for the presence of myocardial ischemia or infarction, because cardiac symptoms may be lacking in this population. Postoperative pain can be severe, given the extensive surgical wound and duration of surgery. Postoperative pain usually is managed with opioids in the perioperative period with transition to patient-controlled analgesia in the early postoperative period. Epidural analgesia may be appropriate for pancreas transplant recipients, although the risks of hypotension, dilutional coagulopathy, and spinal cord hypoperfusion in patients who may have severe microvascular disease have not been quantified. For SPK, the usual postoperative strategies for kidney transplant patients including close monitoring of urine output should be applied.

Surgical complications occur in 7% to 9% of all pancreas transplants and usually require reoperation. Technical complications are associated with the potential for graft loss and patient morbidity.[81] Unlike kidney transplantation, technical complications are the most common cause of pancreas transplant graft failure in the first year after surgery. Graft thrombosis is the most important early complication and requires emergent surgical exploration. Intraabdominal bleeding can occur secondary to coagulopathy induced by anticoagulation for the treatment of graft thrombosis. Late complications include bladder or enteric leaks, intraabdominal sepsis, and rejection. Rejection is the most common cause of long-term graft loss after 1 year and occurs in 15% to 21% of pancreas transplant recipients within 1 year of surgery.[82]

ORGAN MATCHING AND ALLOCATION

The organ matching process for pancreas transplantation is similar to that for kidney transplant organ matching. Blood group and HLA matching are initially performed to match the donor and recipient, followed by a crossmatch at the time of surgery. Most organs allocated for pancreas transplantation are for diabetic recipients younger than 40 years. However, over the past decade, the average transplant recipient's age has increased because of the allocation of more organs for patients with type 2 diabetes.[77] In 2016, the number of pancreas transplants performed in patients over age 50 increased to 240 from 185 the year prior, corresponding with an increase in type 2 diabetics undergoing pancreas transplants.[67]

ANESTHESIA FOR PATIENTS AFTER PANCREAS TRANSPLANTATION

After successful pancreas transplantation, long-term normoglycemia is expected. For patients with a history of previous pancreas transplant presenting for surgery, a comprehensive posttransplant history of any episodes of surgical complications and episodes of rejection should be obtained. Blood glucose concentrations should be measured on the day of surgery. A detailed history and review of medical records focusing on CAD, renal disease, and vascular disease is critical. Although the end-organ progression of diabetes is favorably impacted by pancreas transplant, pancreas transplant patients have a high prevalence of these conditions compared to the general population. Disease progression can occur despite successful pancreas transplantation. Therefore, the preoperative cardiac evaluation for the post-pancreas transplant patient undergoing surgery should be guided by ACC/AHA Guideline.[28]

Liver Transplantation

In 1963, shortly after the effectiveness of azathioprine and prednisone was established for renal transplantation, Dr. Thomas Starzl performed the first human liver transplant.[83] The recipient, a 3-year-old child with biliary atresia, died in the operating room from massive hemorrhage caused by venous collaterals and uncontrollable coagulopathy. Four years later, Starzl performed the first successful transplant in an 18-month-old infant with hepatocellular carcinoma. The advent of cyclosporine in 1979, followed by the 1983 pronouncement of the National Institutes of Health Consensus Conference that liver transplantation was no longer experimental, ushered in the era of liver transplantation. Over the ensuing decades, liver transplantation centers were established around the world, and the field matured following continued improvements in surgical technique, immunosuppression, and the management of coagulopathy and infections.

The number of disciplines that have contributed to the advances in liver transplantation illustrates the team approach involved in the care of the liver transplant recipient. Hepatologists, surgeons, nephrologists, specialists in critical care medicine and infectious disease, anesthesiologists, pediatricians, radiologists, and pathologists have important roles. Key team members extend beyond physicians and include transplant coordinators, nurses, blood bank personnel, and procurement organizations.

Liver transplantation is unique among abdominal organ transplants in that a dedicated team is typically involved because of the unique challenges encountered during liver transplant surgery. The United Network of Organ Sharing (UNOS), which manages the U.S. organ transplant system under contract with the U.S. Department of Health and Human Services, recognizes the important role of anesthesiologists in the perioperative care of liver transplant candidates. In 2011, UNOS instituted a requirement that U.S. liver transplant programs designate a Director of Liver Transplant Anesthesia who meets qualifications based on experience and training. These qualifications parallel similar requirements for the transplant surgeon and physician (hepatologist). In addition, UNOS delineated the clinical responsibilities of the Director of Liver Transplant Anesthesia, which include preoperative assessment of transplant candidates, participation in candidate selection, intraoperative management, postoperative visits, and participation in mortality and morbidity conferences.[84] Lastly, the director is expected to maintain current knowledge in the field of transplant anesthesia by participating in continuing medical education activities related to transplantation.

INDICATIONS FOR LIVER TRANSPLANTATION

Liver transplantation is the only definitive treatment for decompensated cirrhosis secondary to hepatitis C virus (HCV) and alcoholic liver disease, unresectable primary hepatic malignancies, acute liver failure (ALF), and metabolic disease including non-alcoholic fatty liver disease (NAFLD). Of these indications, the category other, which includes patients with NAFLD, accounted for nearly a third (31%) of adult liver transplants performed in the United States in 2016, followed by alcoholic liver disease (24%), HCV (18%), hepatocellular carcinoma (14%), cholestatic disease (9%), and ALF (3%) (Fig. 60.8).

Chronic liver disease and cirrhosis is the fourth leading cause of death in the United States for individuals aged 45 to 64 years, accounting for 4.2% of deaths in this age group. It is surpassed only by cancer, heart disease, and accidents (unintentional injury). Among all age groups, liver disease accounted for more than 29,000 deaths in 2015, making it the 12th leading cause of death.[85]

TRENDS IN LIVER TRANSPLANTATION

The number of adult liver transplants in the United States increased to over 7800 in 2016, a 10% increase from the prior year and a doubling since 1998. European transplant centers perform a similar number of transplants per year (approximately 7000 in 2013) for similar indications.[86] The increase in transplants is attributable to an increased number of deceased donors. In 2016, graft survival continued to improve, with a 1-year failure rate of 10%. Five-year patient survival reported in 2016 was 86% in the United States, which represents an improvement from 74% reported in 2015.[87,88]

Advances in the treatment of chronic liver disease, particularly antiviral therapy, led to a declining number of transplants for hepatitis C, which as of 2016 was no longer the most common indication for liver transplantation.[87] Over the past decade, the proportion of transplants performed for obesity-related fatty liver (NAFLD) is increasing. With the sharp reduction in transplants for HCV, NAFLD has overtaken HCV as the most frequent indication for transplantation. However, despite these advances, when life-threatening complications of liver failure such as encephalopathy, ascites, gastrointestinal bleeding, or uremia develop, survival is significantly improved by liver transplantation (90% 1-year survival) compared with

medical therapy (Table 60.1). Referral for liver transplantation is appropriate in the presence of an index complication of cirrhosis.

During the past decade, the number of patients (adult and pediatric) living with a functioning liver transplant more than doubled, from 30,000 in 2001 to nearly 80,000 in 2015.[88,89]

The median time to transplant in the United States for the period ending in 2015 was 11.3 months, the shortest waiting time in recent history.[87]

Over the past decade, the proportion of recipients aged 65 years or older continued to increase. This age group received over 20% of liver transplants performed in the United States in 2015.[87]

Despite an increase in organs available, the number of waitlisted candidates has exceeded 13,000 for each of the last 3 years. Waitlist mortality remains a concern with 10% to 12% mortality over the same period.[87] Responses to these concerns have resulted in the use of expanded-criteria donors, including grafts donated after cardiac death, which increased from less than 2% of liver transplants in 2001 to 6% in 2011, where it remained in 2015.[87] Living donation has decreased over the past 10 years, particularly for adult recipients. In 2001, more than 400 living donor grafts were transplanted into adult recipients. In 2015, fewer than 300 adults received living donor grafts. This change highlights the concern over postoperative complications in living donors, particularly those providing a larger liver mass, as is the case with right lobe donation. Two living donor deaths were reported in 2010, further illustrating the risk to living donors.

The number of pediatric liver transplants in the United States has been stable at 500 to 600 per year over the past several years (2002-2015). During the same period, approximately 10% to 15% of pediatric recipients in the United States received grafts from living donors, down from 20% to 25% in the prior decade.[89] The most common indication for transplant in pediatric recipients is cholestatic disease (43%), followed by metabolic disease (15%), ALF (4%), and hepatoblastoma (2%).[87] The European Liver Transplant Registry reports similar numbers of pediatric recipients, approximately 10% of the total number of liver recipients.[90]

PATHOPHYSIOLOGY AND EVALUATION FOR LISTING

Cirrhosis is the end product of chronic parenchymal inflammation and necrosis, which results in fibrosis and disruption of hepatic architecture. Resistance to blood flow leads to portal hypertension and the formation of vascular shunts between portal and systemic veins.[91] When the pressure gradient between the portal and hepatic veins exceeds 10 to 12 mm Hg, portal hypertension is severe, and complications such as ascites, esophageal variceal bleeding, encephalopathy, and hepatorenal syndrome (HRS) occur. Decompensated cirrhosis affects nearly every other organ system.[92] The preoperative assessment of liver transplant candidates requires a knowledge of the pathophysiologic changes associated with decompensated cirrhosis.

Cardiovascular Complications

Hyperdynamic circulation—characterized by a high cardiac output, low arterial blood pressure, and low systemic vascular resistance—is the hallmark of end-stage liver disease. Patients appear well perfused despite systolic arterial pressures less than 100 mm Hg. Pulmonary arterial pressures may be mildly elevated because of increased flow;

however, the pulmonary vascular resistance (PVR) is usually within the normal range. These patients have an elevated intravascular volume that is sequestered into a dilated splanchnic vascular bed. The effective circulating volume is typically reduced.

Hyperdynamic circulation is the result of portal hypertension-induced production of vasodilators such as natriuretic peptides, vasoactive intestinal peptide, endotoxin, glucagon, and particularly nitric oxide.[93] Elevated production of nitric oxide has been observed to precede the formation of the hyperdynamic circulation in cirrhosis. The overproduction of vasodilators is responsible for reduced circulatory responsiveness to sympathetic stimulation.[94] Clinically, this frequently results in a need for increased doses of vasopressors.

In addition, patients with cirrhosis can have other cardiac functional abnormalities that are not immediately apparent in the baseline state. These abnormalities define a condition termed *cirrhotic cardiomyopathy* and include systolic and diastolic dysfunction, cardiac resistance to β-adrenergic stimulation, and electrophysiologic abnormalities. Systolic incompetence is revealed by physiologic or pharmacologic stress and is manifested by an inability to increase cardiac output in response to exercise, and an inability to increase ejection fraction despite an increase in end-diastolic volume. The severity of cardiac dysfunction seems to be correlated directly with the severity of liver disease.[95] Diastolic dysfunction has been described in patients with cirrhosis as well, on the basis of diagnostic echocardiographic findings of abnormalities in transmitral flow during diastole. These abnormalities consist of a decrement or reversal of the E/A wave ratio and prolongation of E wave deceleration time, reflecting ventricular resistance to diastolic filling. Diastolic dysfunction manifests as sensitivity to changes in cardiac filling and results in vulnerability to heart failure.

Autonomic dysfunction is present in a significant proportion of cirrhotic patients. It presents as chronotropic and hemodynamic incompetence in response to hemodynamic challenges. Prolonged QTc interval is also observed in patients with cirrhosis, and care should be taken when treating these patients with drugs known to prolong the QT interval.[96]

Risk factors for CAD in patients with cirrhosis are similar to those of other patient populations: hypertension, dyslipidemia, age, gender, and obesity. However, NAFLD has been recognized as an increasingly important cause for transplantation and carries with it the risks of obesity, diabetes, and chronic inflammatory state. The optimal test for identifying cirrhotic patients with significant CAD is unclear. Because many of these patients cannot exercise, pharmacologic stress testing is most commonly used. Unfortunately, studies investigating the predictive value of noninvasive functional testing, particularly DSE, have generally shown poor sensitivity and varying negative predictive value (75%-89%).[97] Thus, among liver transplantation candidates, consideration should be given to proceeding with coronary angiography if the patient is judged to have a high likelihood of CAD.[98] For less complex surgeries, however, this may not be warranted. There is evidence that patients with treated CAD have posttransplant survival similar to patients without angiographic evidence of CAD.[99]

Pulmonary Complications

As many as 50% to 70% of patients with chronic liver disease complain of shortness of breath.[100] The differential diagnosis includes ventilation-perfusion abnormalities associated with underlying obstructive airways disease, fluid retention, pleural effusion, and decreased lung capacities secondary to large volume ascites. α-1 antitrypsin deficiency has both lung and liver manifestations, as does cystic fibrosis. In addition, there are two types of vascular abnormalities unique to the setting of portal hypertension, and they have significant morbidity and mortality. These abnormalities, hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN), are unique entities that have discrete implications on liver transplant candidacy.

HPS is present in up to 20% of patients who present for liver transplantation.[101] The diagnostic criteria for HPS include portal hypertension, PaO_2 less than 70 mm Hg on room air (or alveolar-arterial oxygen gradient greater than 15 mm Hg), and evidence of intrapulmonary vascular dilation (IPVD).[102,103] Demonstration of IPVD can be made by contrast-enhanced echocardiography or by perfusion lung scanning using technetium-labeled macroaggregated albumin. In the absence of HPS, microbubbles and albumin macroaggregates injected into the venous circulation are trapped by the pulmonary capillary bed. The delayed (more than three cardiac cycles) appearance of microbubbles in the left atrium (on echocardiography) or increased (>5%) extrapulmonary uptake of technetium-labeled macroaggregated albumin suggests the presence of IPVD, which results in a massive increase in pulmonary capillary diameter, from between 8 to 15 μm and 50 to 500 μm. This increase, together with the usually hyperdynamic circulation of the cirrhotic patient, allows insufficient time for oxygen diffusion through the entire stream of capillary blood. As a result, the central stream of poorly oxygenated blood is functionally shunted. This lesion is typically correctable with the administration of oxygen. Because IPVDs predominate in the bases of the lungs, standing worsens hypoxemia compared with the supine position (orthodeoxia).

The natural history of HPS is usually one of progressive hypoxemia. Liver transplantation can be expected to correct hypoxemia in greater than 85% of patients, although it may take up to 1 year to do so.[104] In patients with HPS, survival with transplantation is considerably more frequent than without transplantation. Previously, $PaO_2 \leq 50$ mm Hg was considered a predictor of increased mortality with or without transplantation. However, in the largest single-center series of liver transplantation for HPS, the overall 5-year survival was 76%, comparable to transplantation in patients without HPS.[105] These findings suggest that timely transplantation in patients with HPS results in positive outcomes. Accordingly, allocation exception points have been assigned to patients with HPS and room air $PaO_2 < 60$ mm Hg.[106]

PPHTN is defined as pulmonary hypertension in the presence of portal hypertension in a patient without other predisposing factors. The European Respiratory Society Task Force on Hepatopulmonary Disease diagnostic criteria are: (1) clinical evidence of portal hypertension with or without hepatic disease; (2) mean PA pressure of 25 mm Hg at rest or 30 mm Hg during exercise; (3) mean PA occlusion pressure less than 15 mm Hg or transpulmonary gradient

TABLE 60.2 Right Heart Catheterization Data From Four Representative Patients With Cirrhosis and Similar Elevations in Mean Pulmonary Artery Pressure

Patient	Mean PA Pressure (mm Hg)	Pulmonary Capillary Wedge Pressure (mm Hg)	Cardiac Output (L/m)	Pulmonary Vascular Resistance (dyn s cm^{-5})	Diagnosis
1	35	15	5	320	Primary pulmonary hypertension
2	35	15	10	160	Hyperdynamic circulation
3	35	25	5	160	Fluid overload
4	35	25	10	80	Fluid overload in a patient w/hyperdynamic circulation

Note that only the first patient has primary pulmonary hypertension, as evidenced by elevated pulmonary vascular resistance.
PA, Pulmonary artery.

(mean PA pressure minus wedge pressure) greater than 12 mm Hg; and (4) PVR greater than 240 dyn·s·cm^{-5} or 3 Wood Units.[107]

The requirement for calculation of the PVR is a reflection of the fact that many patients with cirrhosis have mildly elevated mean pulmonary arterial pressure based simply on an elevated cardiac output (Table 60.2). Mild, moderate, and severe PPHTN are defined by mean PA pressure less than 35 mm Hg, 35 to 50 mm Hg, and greater than 50 mm Hg, respectively.

The prevalence of PPHTN is 2% in a population of patients with known portal hypertension,[108] as compared with 0.13% in an unselected population.[109] The prevalence is 4% to 6% among liver transplant candidates.[110] The occurrence of PPHTN is unrelated to the severity of the underlying liver disease. Similar to HPS, the symptoms of PPHTN are nonspecific, commonly consisting of dyspnea, generalized weakness, and decreased exercise tolerance.

The single best screening study for PPHTN is two-dimensional transthoracic echocardiography, which estimates right ventricular systolic pressure using the velocity of the tricuspid regurgitant jet. In the absence of pulmonary valvular stenosis, right ventricular systolic pressure is a good estimate of pulmonary arterial systolic pressure. Transthoracic echocardiography screening has a sensitivity of 97% and a specificity of 77% in diagnosing moderate to severe PPHTN in patients undergoing pretransplantation workup.[111] Right-sided cardiac catheterization is necessary, however, to confirm elevated pressures and to measure PVR.

Moderate and severe PPHTN are associated with increased mortality during liver transplantation. In a multicenter study of 36 patients with PPHTN who underwent liver transplantation, more than one-third of the patients died during the hospitalization (within 3 weeks of surgery). Nonsurvivors (12 of 13 patients) had mean PA pressures greater than 35 mm Hg.[112] In addition to elevated mortality, the effect of successful liver transplantation on the natural course of PPHTN is unpredictable. Some patients experience a resolution with transplant, some continue to require medical therapy, and in some cases PPHTN worsens. This suggests that patients with moderate or severe PPHTN should undergo treatment for PPHTN before liver transplantation.

Vasodilator therapy consists of prostanoids (epoprostenol), phosphodiesterase inhibitors (sildenafil), and endothelin antagonists (bosentan). Calcium channel blockers, often used in noncirrhotic patients with pulmonary hypertension, are contraindicated in patients with cirrhosis because the associated mesenteric vasodilation worsens portal hypertension. Patients who respond to treatment sufficiently to reduce their mean PA pressure below 35 mm Hg and PVR below 400 dyn·s·cm^{-5} should be considered suitable transplant candidates.[112,113]

Renal Dysfunction

Renal dysfunction in patients with cirrhosis is the result of renal hypoperfusion and avid retention of sodium. HRS is a prerenal abnormality caused by circulatory derangements of advanced cirrhosis. It is considered a functional disorder, based on successful transplantation of kidneys from patients with HRS.[114] Renal function is an important risk factor for mortality, a fact that is emphasized by its presence as one of only three variables used in calculating the Model for End-Stage Liver Disease (MELD) score.

In addition to HRS, patients with cirrhosis are also at risk for other causes of renal dysfunction, such as parenchymal renal disease, sepsis, nephrotoxicity, and hypovolemia. HRS is a diagnosis of exclusion, and other treatable causes must be ruled out. HRS accounts for only about one-fourth of the cases of acute kidney injury in hospitalized cirrhotic patients.[115] In patients with cirrhosis and ascites, the incidence of HRS is nearly 40% at 5 years.[116]

HRS is caused by the local production of vasodilators, particularly nitric oxide, in patients with portal hypertension. Splanchnic vasodilation leads to a decrease in the effective circulating blood volume and a decrease in arterial blood pressure, which activates the sympathetic, renin-angiotensin-aldosterone, and vasopressin systems. The net result is a severe reduction in renal perfusion and glomerular filtration.

Type I HRS is characterized by rapidly progressive renal failure and a doubling of serum creatinine over 2 weeks after a precipitating cause such as spontaneous bacterial peritonitis, sepsis, gastrointestinal bleeding, or surgical stress. Patients with type I HRS have a median survival of 2 to 4 weeks without therapy.[117,118] Patients with type II HRS have a median survival of about 6 months.[119]

Although renal vasoconstriction is the proximate cause of HRS, therapy aimed at directly increasing renal perfusion by the use of prostaglandins, dopamine agonists, or endothelin antagonists has not proven to be successful. Vasoconstrictor therapy targeting the underlying splanchnic vasodilation is more effective.[120]

These therapies include arginine vasopressin, somatostatin, and α-agonists such as norepinephrine and midodrine, combined with volume expansion. Terlipressin, the most studied vasopressor for HRS, is in phase 3 trials in the United States.[121-123]

Placement of a transjugular intrahepatic portosystemic shunt (TIPS) lowers portal pressures and can decompress the splanchnic circulation. Pilot studies have shown that a TIPS is capable of reversing both types of HRS, but because of extensive exclusionary criteria in trials and the risk of worsening hepatic encephalopathy (HE), a TIPS might not be suitable for all patients with HRS.[124]

Liver transplantation is the definitive therapy for HRS. For patients with HRS who are transplant candidates, renal replacement therapy is the typical bridge to transplantation. Although renal recovery is anticipated, 35% of patients with pretransplant HRS will continue to require support in the immediate postoperative period, compared with 5% of patients without pretransplant HRS.[125] During the First International Liver Transplantation Society Expert Panel Consensus on Renal Insufficiency in Liver Transplantation, it was recommended that patients who received dialysis at least twice weekly for more than 6 weeks before liver transplantation be considered for combined liver-kidney transplantation.[126]

Hepatic Encephalopathy

HE is a serious, albeit reversible neuropsychiatric complication that is a feature of both chronic and acute liver disease. Manifestations range from subtle, subclinical abnormalities to overt neurologic and behavioral derangements that are readily apparent at the bedside.

HE has been attributed to hyperammonemia, but the severity of HE does not necessarily correlate with ammonia levels. A number of other factors and mechanisms also contribute to HE, including other gut-derived neurotoxins, γ-aminobutyric acid (GABA) and other endogenous GABA-receptor agonists, oxidative stress, inflammatory mediators, hyponatremia, and abnormal serotonin and histamine neurotransmission.[127,128]

The initial step in evaluating the patient with liver disease who presents with encephalopathy is to rule out causes other than HE. The differential diagnosis includes other metabolic causes such as uremia, sepsis, glucose and electrolyte abnormalities, and endocrinopathies. Structural and vascular central nervous system lesions or infections should also be considered. Because cirrhotic patients are exquisitely sensitive to sedative medications and have impaired hepatic (and often renal) metabolism, a careful search for possible drug-related encephalopathy should be undertaken. Once other potential causes have been eliminated, the next step should be a systematic search for an underlying cause or precipitating factor, such as infections (e.g., spontaneous bacterial peritonitis, sepsis) or gastrointestinal bleeding.

Therapy to reduce ammonia levels consists of the nonabsorbable disaccharide lactulose and nonabsorbable antibiotics such as neomycin, metronidazole, and rifaximin. Nonabsorbable antibiotics appear to be equally effective to nonabsorbable disaccharides but concerns about toxicity associated with long-term administration limit their use.

Ascites

Ascites is the most common complication of cirrhosis leading to hospitalization.[129] Patients who have ascites should be referred for liver transplantation evaluation in the absence of contraindications. Nonhepatic causes account for 15% of ascites and include malignancy, cardiac failure, renal disease, pancreatitis, and tuberculosis. Paracentesis is an important aid in diagnosis.[130] A serum-ascites albumin gradient greater than 1.1 mg/dL indicates portal hypertension with 97% accuracy.[131] Rapid correction of hyponatremia is undesirable because patients with cirrhosis are at risk for central pontine myelinolysis, a potentially devastating neurologic complication. Observations in liver transplant recipients suggest limiting correction to less than 16 mEq/L during the intraoperative period.[130]

Once ascites becomes refractory to maximum standard medical therapy, therapeutic options are limited and include serial paracentesis, liver transplantation, TIPS placement, and peritoneovenous shunt.

Risk factors for development of spontaneous bacterial peritonitis include a prior episode of this acute infection, gastrointestinal bleeding, and an ascites albumin level of less than 1.5 g/dL. Long-term antibiotic prophylaxis with norfloxacin or trimethoprim/sulfamethoxazole is recommended for patients who have survived an episode of spontaneous bacterial peritonitis.[129]

Varices

Cirrhosis increases portal pressure as a result of chronic inflammation. Fibrosis and regenerative nodules cause resistance to splanchnic flow and lead to formation of portosystemic collaterals. Progression of portal hypertension leads to increased local production of nitric oxide and exacerbates splanchnic vasodilation. Rupture of the high-pressure collaterals that are formed is a highly lethal and feared complication of portal hypertension.

Portal hypertension is diagnosed by measurement of the wedged hepatic venous pressure (WHVP). Although this is not a direct measure of portal pressure, WHVP has been demonstrated to correlate well with portal pressure.[132] This measurement is taken by advancing a catheter into a hepatic vein to the wedge position. To correct for the contribution of increased intraabdominal pressure from ascites, a free hepatic venous pressure or an inferior vena cava (IVC) pressure should be subtracted from the measured WHVP to give the hepatic venous pressure gradient (HVPG). A normal HVPG is 3 to 5 mm Hg. Patients with varices have HVPGs of 10 to 12 mm Hg or greater.

Esophagogastroduodenoscopy is the gold-standard procedure for diagnosing varices. Risk for variceal bleeding correlates with size of varices, presence of red wale marks, and variceal pressure (i.e., HVPG). Therapeutic decisions are based on these observations and measurements. Nonselective β-adrenergic blockers reduce portal pressure by two mechanisms: a decrease in cardiac output (β_1) and splanchnic vasoconstriction (β_2). For patients who cannot tolerate β-adrenergic blockers or in whom they are contraindicated, another option for primary prophylaxis of variceal bleeding is endoscopic ligation. The TIPS procedure had been considered a backup procedure for variceal bleeding, but recently has been advocated for early treatment in select patients.[133] However, TIPS is associated with a higher incidence of encephalopathy; despite this, TIPS may decrease mortality in select patients.[133]

Acute variceal bleeding should be managed with a combination of intravascular volume resuscitation, correction of severe coagulopathy, pharmacologic manipulation of portal pressure, and endoscopic variceal ligation. Aggressive intravascular volume replacement can lead to resistant or recurrent bleeding because bleeding is a pressure-related phenomenon.[134,135] Elective intubation of the trachea for airway protection is often warranted. Medications to reduce portal pressure include vasopressin and somatostatin. Although β-adrenergic blockers can reduce portal pressures, their effect on systemic pressures makes them undesirable in this setting. Early endoscopic variceal ligation in combination with pharmacotherapy is the preferred treatment for acute variceal bleeding. Balloon tamponade can be effective for resistant variceal bleeding, but is associated with significant complications, including esophageal rupture and aspiration. It is recommended as a bridge to more definitive therapy such as surgical shunt, TIPS, or liver transplantation.

Hemostasis

Hemostasis is a dynamic process that is the product of interaction between coagulation, platelets, and fibrinolysis, resulting in the formation and revision of clot. Liver disease affects all of these components, both quantitatively and qualitatively. The liver is the site of synthesis for all procoagulant and anticoagulant factors, with the exception of tissue thromboplastin (III), calcium (IV), and von Willebrand factor (VIII). It is also the site for clearance of activated factors.

Patients with cirrhosis are customarily considered to have a bleeding diathesis based on abnormal results in conventional tests of coagulation, such as prothrombin time (PT) and partial thromboplastin time (PTT). However, such tests reflect the activity of only a portion of the procoagulant factors, and do not consider the concomitant decrease in anticoagulant factors, which are not assessed. It is the balance of procoagulant and anticoagulant forces, not the isolated measurement of either portion of the coagulation system, that indicates the effective generation of thrombin. Not surprisingly, PT and PTT abnormalities correlate poorly with bleeding complications following invasive procedures, such as liver biopsy.[136] There is evidence that decreased levels of protein C in cirrhotic patients balance the decreased levels of procoagulants, which can leave thrombin generation in vivo unaltered.[137]

If procoagulants predominate because of disproportionate reductions of anticoagulants (protein S and C, antithrombin III), accompanied by an increase in procoagulants (FVIII), a hypercoagulable state results.[138,139] This possibility is supported by studies reporting venous thromboembolism associated with cirrhotic and noncirrhotic liver disease.[140,141]

Thrombocytopenia is a well-known feature of cirrhosis. The primary cause is splenic sequestration in the setting of portal hypertension. Elevated levels of von Willebrand factor compensate for decreased platelets counts, augmenting the platelet–endothelial cell interaction on vessel walls.

The fibrinolytic system in cirrhotic patients has many abnormalities, which may account for accelerated fibrinolysis. The liver is the site of tissue plasminogen activator clearance, and elevated tissue plasminogen activator levels have been noted in patients with cirrhosis.[142] The liver is also the site of synthesis for plasmin inhibitors, such as plasmin activator inhibitor-1 and thrombin-activatable fibrinolysis inhibitor. A balance of factors that promote and inhibit fibrinolysis is desired. Commonly used studies for assessing the presence and severity of accelerated fibrinolysis include euglobulin clot lysis time and thromboelastography (TEG).

Disseminated intravascular coagulation (DIC) is primarily a thrombotic diathesis, followed by widespread secondary fibrinolysis. As factors are consumed, DIC becomes a bleeding diathesis of factor and platelet deficiency. Whether or not DIC is a feature of stable chronic liver disease is controversial. Standard laboratory tests cannot distinguish between consumption and decreased synthesis, and so have little utility. Instead, assays to assess for excessive thrombin production are used. These assays include the cleaved by-products of coagulation factor activation such as prothrombin fragment F1+2, fibrinopeptide A, and thrombin-antithrombin complexes. These assays suggest that overt DIC is not a feature of stable chronic liver disease[143]; however, accelerated intravascular coagulation and fibrinolysis has been described, which is a low-grade consumptive process.[144] Patients who exhibit accelerated intravascular coagulation and fibrinolysis are at increased risk of DIC in the presence of a known stimulus, such as sepsis or spontaneous bacterial peritonitis.

OBESITY AND SARCOPENIA

Liver disease is associated with altered protein, carbohydrate, and lipid metabolism. Protein calorie malnutrition is present in over 50% of decompensated cirrhotics.[145] A standardized battery of questions and physical exam findings can be used to evaluate nutritional status. Among the available tools is the Subjective Global Assessment and Royal Free Hospital Global Assessment,[146,147] which uses a composite of several variables. Muscle wasting and fat depletion are highly correlated with scores based upon these tools. Triceps skinfold thickness, a marker of fat reserve, is associated with malnutrition. A value of less than the fifth percentile is diagnostic of severe malnutrition.[148] In addition, computed tomography has been evaluated as an assessment method for sarcopenia (muscle loss), which correlates with pretransplant mortality.[149]

NAFLD refers to the presence of hepatic steatosis in the absence of known causes for hepatic fat deposition. It is subdivided into nonalcoholic fatty liver (NAFL) and nonalcoholic steatohepatitis (NASH); the latter is distinguished from the former by the presence of inflammation identical to that of alcoholic steatohepatitis. Factors associated with disease progression include body mass index, diabetes, and increasing age. As the most common indication for liver transplantation is now NAFLD, the body mass index of transplant recipients has risen in parallel.[87]

SURGICAL PROCEDURE

Preoperative Considerations

In 2015, the median time to transplant in the United States was 11 months (interquartile range, <1 month to <1 year).[87] As a result, a transplant candidate can be months removed from their initial evaluation when a suitable donor graft is identified. Therefore, the prospective recipient's evaluation should be reviewed while arrangements are made for donation. Candidates undergo an extensive preoperative assessment by multiple teams that typically include the surgical team, hepatologists, cardiologists, pulmonologists, psychiatrists, and social workers. In the event of unique comorbidities, additional consultants are involved as needed. Of particular interest to the anesthesiologist are interim changes in health status, hospitalizations (the possibility of infection should be considered with new-onset encephalopathy, variceal bleed, ascites, or hemodynamic deterioration), details of the initial and any subsequent cardiopulmonary evaluation (assess for the presence of coronary disease, heart failure, pulmonary hypertension, or arrhythmia), and renal status (acute kidney injury).

Unlike chronic liver disease, ALF is associated with increased intracranial pressure (ICP); preoperative evaluation and treatment focuses on the prevention of irreversible neurological injury. See section on "Acute Liver Failure" later.

Futility. The allocation policy in the United States, adopted by many programs worldwide, uses MELD scores to prioritize allocation of grafts to the sickest patients. Modifications to this MELD score have been proposed in efforts to improve the score's predictive ability.[150,151] This policy, however, is in tension with saving as many patients as possible, since outcomes in high-MELD patients are, in general, inferior. Attempts to define futility have led to multiple definitions, such as 90-day mortality[152] and less than 50% survival at 5 years. However, these definitions are subjective, as they require projections based upon age, coexisting disease, and physical frailty, factors not captured by the MELD score. A recent review provides an in-depth discussion of futility.[153] The concept of futility is likely to evolve, and hopefully 1 day provide objective criteria that can be reliably implemented.

Patients predicted to have decreased survival 1 year after transplant represent a high-risk group and include patients undergoing retransplantation or those supported by mechanical ventilation, infusions of vasopressors, and renal replacement therapy.[3] Patients dependent on renal replacement therapy will benefit from preoperative dialysis; patients with oliguria, hyperkalemia, or acidemia, may benefit from intraoperative renal replacement therapy.[154,155] Intraoperative renal replacement is not without risk; intraoperative fluctuations in clotting was associated with filter circuit clotting in 40% of patients in one series.[154] In our experience, circuit clots may suggest a hypercoagulable state associated with cardiac thromboembolic events.

A protocol should be in place to notify the blood bank of the pending transplant, which results in the setup of red blood cells and plasma in a volume according to institutional protocol. If any delay is anticipated in the availability of blood products, for instance in the event of antibodies, the blood bank personnel should notify the transplant coordinator and anesthesiologist. In the presence of red cell antibodies, our institutional policy is to set up compatible red cells for the start and completion of the transplant, and to use compatibility-unknown red cells in the event of large transfusion requirements.

The surgical procedure is divided into three distinct stages. During the preanhepatic or dissection stage, the liver is mobilized and vascular structures (suprahepatic and infrahepatic vena cava, portal vein, and hepatic artery) are identified. The anhepatic phase begins with clamping of these vessels and hepatectomy of the native liver and continues during the implantation of graft. Reperfusion, usually via the portal vein, starts the neohepatic phase, which continues through completion of the remaining vascular anastomosis (usually the hepatic artery), anastomosis of the bile duct, hemostasis, and abdominal closure.

Intraoperative Management

The intraoperative course of liver transplantation may be complex and prolonged; anesthesia teams are crucial to the success of programs. Intraoperative personnel and monitoring vary among liver transplant services based on institutional practice, caseload, and resources. Most centers allocate two anesthesia providers for liver transplants; however, the qualifications of these providers vary. A typical arrangement in an academic setting consists of an attending anesthesiologist experienced in liver transplantation and a senior resident. In private practice settings the second provider may be a second anesthesiologist, a certified nurse anesthetist, a licensed healthcare provider such as a perfusionist, or some combination of these. In general, most centers employ dedicated liver transplant anesthesia groups. Members of these groups are highly trained and experienced in the management of liver transplantation and often focus research and academic efforts toward liver transplant anesthesia. Liver transplant anesthesia fellowships dedicated to training physicians for careers in liver transplant anesthesia have been established in many centers. There is evidence that the experience of the anesthesia provider affects outcome; one series demonstrated that postoperative mortality was increased when the anesthesiologist had performed fewer than six liver transplant anesthetics.[156]

Anesthesia typically begins with a rapid-sequence induction. Liver transplant patients are considered at high risk for aspiration of gastric contents because of the emergent nature of the surgery, preoperative administration of oral immunosuppressants/bowel decontamination antibiotics, and the presence of ascites. An arterial catheter is placed either before induction of anesthesia or immediately thereafter, depending on the hemodynamic stability of the patient prior to induction. Some centers routinely place femoral arterial lines because of the concern that radial arterial monitoring may underestimate central arterial pressure during episodes of intense vasodilation or in patients receiving high-dose vasopressors. However, there are no clear data in liver transplant patients to definitively recommend the use of central arterial pressure monitoring over radial monitoring.[157] Large-bore intravenous access is necessary as rapid blood loss, large fluid shifts, and hemodynamic instability are frequent. Most centers place large single- or double-lumen introducers centrally, or in the event of significant concern for blood loss (as is the case for retransplantation or in patients with extensive prior abdominal surgery) two introducers may be placed in a central vein. Sites designated for venovenous bypass (VVB) are avoided, if possible. There are differences between institutions regarding the routine use of PA catheters. In patients with a history of PPHTN or in those with echocardiographic evidence of elevated PA pressures, PA catheter placement may be necessary to calculate PVR prior to incision; the results may impact the patient's candidacy for transplant.[158] In the patient with elevated PA pressures or borderline PVR, a PA catheter may help guide therapy during the perioperative period. However, if the recipient has had a recent negative evaluation for pulmonary arterial hypertension, a PA catheter may not be deemed necessary by some practitioners. Transesophageal echocardiography is increasingly used during liver transplant as it provides continuous cardiac imaging and may facilitate the rapid diagnosis of critical events such as ventricular failure, myocardial ischemia or infarction, pericardial tamponade, and intracardiac thrombosis. A recent survey demonstrated that transesophageal echocardiography is utilized widely in U.S. liver transplant centers.[159] Transesophageal echocardiography appears to be associated with a low likelihood of hemorrhagic complications, even in the presence of esophageal varices.[160] Some liver transplant centers avoid PA catheter insertion in the event that transesophageal echocardiography is used. New technologies, including arterial pressure waveform analysis and three-dimensional echocardiography, do not correlate with thermodilution-derived parameters and are not currently advocated for routine use intraoperatively.[161,162]

A rapid infusion system capable of high transfusion flow rates (>500 mL/min) is typically used. Such systems incorporate a reservoir, pump, filters, heat exchanger, and safety features designed to avoid and monitor for the presence of blood or air embolism, hypothermia, and line occlusion. Rapid infusion systems are important for volume replacement, transfusion management, and maintenance of normothermia.

The effects of the anesthetic technique on patient outcome are unknown. At many centers a balanced anesthetic is used; this typically consists of a volatile anesthetic in low to moderate concentrations (0.5-1.0 minimum alveolar concentration [MAC]) to ensure unconsciousness, whereas a synthetic opioid, often fentanyl, is chosen to blunt the sympathetic response to stimulation and to provide a smooth transition for postoperative analgesia. In recipients with fulminant hepatic failure and cerebral edema, volatile anesthetics are avoided or used cautiously in low concentrations, in many cases with ICP monitoring (see later). In either case, periods of hypotension during the surgery may require temporary decreases of volatile anesthetic concentrations. Midazolam, with minimal hemodynamic effects, can be used for its amnestic effects during these hypotensive periods. Historically, the volatile anesthetic of choice has been isoflurane, which preserves splanchnic blood flow better than previously used volatile drugs.[163] Studies in healthy humans have demonstrated the vasodilatory effects of isoflurane on the hepatic circulation.[164] This beneficial effect on hepatic oxygen supply may be advantageous to the newly reperfused graft. The effects of desflurane on hepatic blood flow have been evaluated with conflicting results. In animals, desflurane decreased total hepatic blood flow in a dose-dependent fashion at concentrations up to 1.0 MAC; however, in a human study that excluded patients with liver disease, liver blood flow was slightly more rapid with desflurane than with isoflurane, although this effect was not statistically significant.[165] Another study compared the effects of sevoflurane and desflurane on hepatic blood flow and hepatocellular integrity in older patients.[166] Both anesthetics resulted in decreases in gastric mucosal pH and increases in cytosolic liver enzymes. The authors conclude that hepatocyte function is well preserved, although their results suggest that splanchnic perfusion and oxygen delivery to the liver are transiently decreased. Whether the increased metabolism of sevoflurane (100-fold that of desflurane) is detrimental to the liver is unknown, but it seems unlikely that the metabolites of sevoflurane cause liver damage.[167] Compound A, a breakdown product of sevoflurane found to be nephrotoxic in animals, has not been shown to cause renal toxicities in humans, even during low-flow sevoflurane administration.[168]

Cisatracurium is an attractive choice for neuromuscular blockade in patients undergoing liver transplantation because of its organ-independent elimination and diminished histamine release.[169] In patients with end-stage liver disease, the volume of distribution of cisatracurium is larger than that in healthy control patients. Hepatic clearance is also increased in patients with liver disease; this results in similar elimination half times and similar duration of action. Other reports have suggested the use of rocuronium during liver transplantation, because the duration of the neuromuscular block appears to be a useful predictor of primary allograft function. All patients whose recovery time was longer than 150 minutes experienced primary graft dysfunction.[170]

Preanhepatic Stage

The preanhepatic stage begins with surgical incision and ends with vascular exclusion and hepatectomy of the native liver. Using conventional caval interposition technique, vascular exclusion of the liver is accomplished by cross-clamping the portal vein, the suprahepatic IVC, the infrahepatic IVC, and the hepatic artery (Fig. 60.9). If a piggyback technique is used, the native retrohepatic vena cava is preserved (Fig. 60.10).

The preanhepatic phase involves dissection and mobilization of the liver and identification of the porta hepatis. With abdominal incision and drainage of ascites, hypovolemia can occur. This should be treated in an anticipatory fashion with colloid-containing fluid to minimize changes in preload. In addition, the dissection phase may be complicated by significant bleeding necessitating massive transfusion and management of hemostasis (see later). Bleeding during this phase of surgery is related to the degree of preexisting coagulopathy, the presence and severity of portal hypertension, and the duration and complexity of the surgical procedure, which is adversely affected by prior abdominal surgery and adhesions.[171,172] The use of vasoactive infusions to maintain end-organ perfusion pressure is common, especially in critically ill patients with underlying cirrhotic cardiomyopathy. Occasionally during the preanhepatic stage, patients may exhibit hostile abdominal anatomy that impedes hepatic resection or may develop severe cardiovascular and metabolic instability that render them inoperable; discussion between the anesthesia and surgical teams to determine if the transplant should be aborted is crucial to prevent futile care in these situations.

In addition to massive transfusion and coagulopathy, the preanhepatic stage may be associated with significant metabolic and acid-base disturbances that require close monitoring and active management. Abnormalities of sodium are not unusual in liver transplant patients; hyponatremia should not be corrected rapidly. A perioperative increase of 21 to 32 mEq/L in the serum sodium level was associated with central pontine myelinolysis in one report, whereas an increase of less than 16 mEq/L was not.[130,173] Citrate intoxication (ionized hypocalcemia resulting from the infusion of citrate-rich blood products in the absence of hepatic function) is avoided by the administration of calcium chloride. Ionized hypomagnesemia also results from citrate infusion, but values of ionized magnesium gradually return to normal after graft reperfusion.[174] The clinical significance of this remains speculative, but cardiovascular function may be affected. Aggressive treatment of hypokalemia is best avoided, particularly in preparation for reperfusion and the associated increase in serum potassium. Hyperkalemia should be avoided by the administration of diuretics and insulin accompanied by glucose or, in the event these are ineffective, by intraoperative dialysis. In the absence of insulin administration, supplemental glucose is usually not required except in pediatric patients or those with severe disease, such as fulminant hepatic failure. Hyperglycemia should be avoided, because glucose levels greater than 180 mg/dL are associated with an increase in surgical site infections in liver transplant recipients.[175] Blood gases, electrolytes, glucose, ionized calcium, and hemoglobin levels should be assessed regularly, and as frequently as hourly in the event of massive blood loss or preexisting abnormalities. Point-of-care testing facilitates rapid turnaround times for laboratory values. Coagulation studies are typically assessed at the beginning of the surgery, after correction of specific deficiencies, after reperfusion, and in the presence of microvascular bleeding.

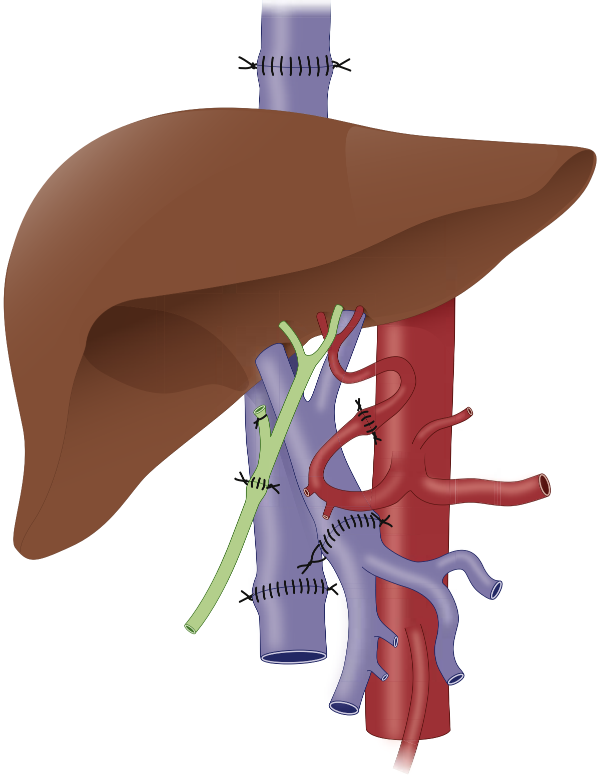

Fig. 60.9 Liver transplantation. Classic caval interposition technique illustrating anastomoses of the suprahepatic and infrahepatic inferior vena cava, the portal vein, the hepatic artery, and the bile duct. (From Molmenti E, Klintmalm G. *Atlas of Liver Transplantation*. Philadelphia: Saunders; 2002.)

The maintenance of urine output is desirable; however, the use of low-dose dopamine for this reason is unproven.[176,177] Hypothermia should be avoided. Core temperature control can be aided with heated VVB during the anhepatic phase. Regardless of whether bypass is used, forced-air warming blankets should be positioned beneath the patient and over the lower and upper body.

(B) Preservation of the native retrohepatic vena cava and hepatic venous cuff anastomosis. (From Molmenti E, Klintmalm G. *Atlas of Liver Transplantation*. Philadelphia: Saunders; 2002.)

Anhepatic Stage

The anhepatic stage begins with the occlusion of vascular inflow to the liver, and it ends with graft reperfusion. Cross-clamping of the suprahepatic and infrahepatic IVC decreases venous return by as much as 50%. VVB diverts IVC and portal venous flow to the superior vena cava via the axillary vein, attenuates the decrease in preload, improves renal perfusion pressure, lessens splanchnic congestion, and can delay the development of metabolic acidosis.[178] However, the use of VVB is not without risk. Air embolism, thromboembolism, and inadvertent decannulation can be fatal or result in significant morbidity.[179] VVB is not uniformly used at all centers. A meta-analysis of three trials failed to reveal any difference in the incidence of renal failure or blood transfusion requirements between patients randomized to VVB compared with patients in whom the technique was not used.[180] The use of the "piggyback" technique, with IVC preservation, decreases the need for VVB.[181]

Hepatectomy is followed by hemostasis and vascular anastomoses of the suprahepatic and infrahepatic IVC and the portal vein. Despite the absence of hepatic clotting factor production during the anhepatic stage, blood loss is usually limited by vascular clamping of the inflow vessels to the liver. However, fibrinolysis may begin during this stage because of an absence of liver-produced plasminogen activator inhibitor, which results in the unopposed action of tissue plasminogen activator. The use of antifibrinolytics varies among centers (discussed later).

Neohepatic Stage

Reperfusion of the graft through the portal vein begins the neohepatic stage. Reperfusion is associated with abrupt increases in potassium and hydrogen ion concentrations, an increase in preload, and a decrease in systemic vascular resistance and blood pressure. Hypothermia, monitored through a centrally placed catheter, is a marker for the presence of graft outflow into the central circulation. Life-threatening hyperkalemia, clinically detectable by changes in the EKG, requires prompt treatment. Calcium chloride and sodium bicarbonate are the drugs of choice for the acute treatment of hyperkalemia. If time permits, albuterol and insulin are also effective. Intraoperative dialysis should be considered early in the procedure for patients with oliguria and elevated potassium levels.

The hallmark of the postreperfusion syndrome (PRS) is systemic hypotension and pulmonary hypertension occurring within the first 5 minutes after reperfusion of the graft. Approximately one in three patients undergoing orthotopic liver transplantation (OLT) have profound hypotension after reperfusion. The cause is uncertain, but a number of factors have been implicated, such as hyperkalemia, acidosis, hypothermia, emboli (air or thrombotic), and vasoactive substances. Risk factors for hyperkalemia in the early postreperfusion period are elevated preanhepatic potassium levels and the use of donated-after-cardiac-death donor organs.[182] One study identified suboptimal grafts (higher degree of steatosis) and graft cold ischemia time as risk factors for PRS.[183] In this study all cases of PRS, defined as mean blood pressure less than 60 mm Hg, occurred in suboptimal donors with graft cold ischemia times longer than 6 hours. The PRS group had higher postreperfusion K^+ levels and lower postreperfusion temperature than in the group without PRS.

In addition, other critical events such as severe, acute bleeding resulting in hemodynamic compromise and necessitating massive transfusion can occur at any point during the surgery. Arrhythmias and intracardiac thromboembolism can also occur at any time intraoperatively, but are more likely after reperfusion.[184,185]

Hepatic arterial anastomosis and biliary reconstruction are generally performed after venous reperfusion, although in pediatric patients the arterial anastomosis may be completed before reperfusion. Signs of graft function that might be observed in the operating room and early postoperative period include decreased calcium requirements, improvement in acidosis, increased urine output, a rise in core temperature, and bile output from the graft.[186]

Management of Transfusion, Hemostasis, and Coagulation

As previously described, end-stage liver disease produces a complex disorder of coagulation that affects both procoagulant and anticoagulant systems, resulting in a fragile state that can lead to either bleeding or thrombosis depending on the clinical conditions of the patient. During liver transplantation, the preexisting coagulopathy of end-stage liver disease may be further impacted by massive transfusion, dilutional coagulopathy, the loss of hepatic synthetic function, a heparin-like coagulopathy following graft reperfusion, and fibrinolysis.[187] The management of coagulopathy and transfusion is crucial in the care of liver transplant patients.

Starting in the preanhepatic phase, drainage of ascites and surgical blood loss necessitate volume resuscitation. In the presence of coagulopathy, fresh frozen plasma may be indicated soon after incision, although some authors have challenged the need for fresh frozen plasma during OLT.[188,189] Prothrombin complex concentrates (PCCs), which contain vitamin K–dependent factors, may be considered as an alternative to plasma transfusion to avoid the risk of transfusion-related acute lung injury and transfusion-associated circulatory overload.[190,191] Several PCCs, containing therapeutic levels of factor II, VII, IX, and X in addition to varying amounts of protein C and S, are available for clinical use.[192] The primary concern related to PCC administration is thromboembolic complications, which vary according to the patient's underlying disease, dosing, and the constituents in each of the commercially available PCC products.[193] Although the reported risk of thrombosis was low (1.4%) in a large study that investigated PCC for the reversal of warfarin in non-liver transplant populations, there are no published randomized controlled trials that have assessed the safety of PCC in liver transplant patients.[194] Another product, recombinant activated factor VII (rFVIIa), was evaluated during liver transplantation and was found to improve coagulation study results, but did not result in a decrease in transfusion requirements.[195,196] rFVIIa has been linked to an increased risk of arterial, but not venous, thromboembolic events.[197] Fibrinogen levels may decrease during liver transplant due to massive bleeding, dilution, and consumptive processes. Fibrinogen-rich components such as cryoprecipitate and fibrinogen concentrates may be indicated for coagulopathic bleeding with documented hypofibrinogenemia. Cryoprecipitate is available in North America and the United Kingdom, while fibrinogen concentrates are employed in Europe.[192] Thrombocytopenia is common in the liver transplant patient, however prophylactic platelet transfusion during liver transplant appears to have limited efficacy for improving coagulation parameters in liver transplant patients.[192] In addition, adverse effects from intraoperative platelet transfusions have been demonstrated in liver transplant patients, including increased rates of acute lung injury as well as increased 1-year graft failure and mortality.[198,199] In general, administration of blood products and/or factor concentrates in liver transplant patients should be for clinically significant bleeding; prophylactic administration is not recommended.[200]

TEG or standard laboratory tests (PT, fibrinogen, and platelet count) are used to guide the correction of coagulopathy.[190,201] Viscoelastic-guided coagulation management has been extensively studied in cardiac surgery patients and has been shown to decrease blood transfusions.[202] Although viscoelastic-guided protocols have been described in liver transplant cohorts, there is less evidence to show that they significantly impact transfusion requirements. In one single-center study of liver transplant patients, a viscoelastic-guided protocol was employed for intraoperative hemostatic management that included the use of PCC and fibrinogen concentrate. The median red blood cell transfusion requirement was low (two units); 29% of patients received platelets and 15% received plasma.[203] However, another single-center comparative study in liver transplant patients showed that a viscoelastic-guided algorithm did not decrease blood transfusions compared to a standard transfusion protocol.[204] Considerable institutional variation exists in transfusion practices for OLT, as do variations in patient acuity as evidenced by MELD scores. Intraoperative blood transfusion has been shown to be a predictor for posttransplant survival in single-center studies, although the reported transfusion thresholds that affected outcome vary.[205-207] Transfusion requirements for liver transplant patients appear to be multifactorial; many donor, recipient, and procedural factors have been shown to impact intraoperative transfusion.[200] Fibrinolysis may contribute to bleeding necessitating targeted therapy during liver transplant. Fibrinolysis is most severe after reperfusion and is caused by abrupt increases in tissue plasminogen activator from graft endothelial cell release. Antifibrinolytic drugs and cryoprecipitate may be required. Since the removal of aprotinin from the world market in 2008, the lysine analogues epsilon-aminocaproic acid and tranexamic acid are typically employed for the treatment of coagulopathic bleeding due to fibrinolysis, although optimal dosages in liver transplant patients have not been determined.[200] Antifibrinolytic therapies have been studied in liver transplant patients to assess their impact on blood transfusion. Three recent studies demonstrated that prophylactic administration of lysine analogues decreased transfusion requirements, although one study showed that antifibrinolytic therapy was associated with a higher risk of deep venous thromboses.[208-210] Although there is no clear evidence that antifibrinolytic therapy produces a hypercoagulable state during liver transplant, major thrombotic complications have been well reported in liver transplant patients.[200] In general, antifibrinolytic therapy should be employed in the setting of significant bleeding with suspected or documented hyperfibrinolysis.[200]

Postoperative Care

The goals of the immediate postoperative period are to ensure a smooth transition from anesthesia and surgery (maintain hemodynamic stability, metabolic homeostasis, adequate analgesia), monitor graft function (transaminase levels, PT, bilirubin levels, bile and urine output, acid-base status), and maintain surveillance for known complications (bleeding, bile leaks, vascular thrombosis, primary nonfunction). The use of steroids leads to hyperglycemia, which can require insulin infusion.

The lack of bile output, accompanied by hemodynamic instability, suggests primary nonfunction of the graft, which may require urgent retransplantation. Conversely, a functioning liver graft facilitates early neurologic recovery, cardiovascular stability, and improved renal function, signs that can occur within hours of the completion of surgery.

Hepatic artery thrombosis can lead to graft necrosis, necessitating retransplantation. Within the first 2 to 3 postoperative days, markedly abnormal transaminase levels are common because of graft ischemia or injury during procurement, preservation, and reperfusion. After this period, hepatic enzyme and bilirubin levels that do not trend downward suggest the possibility of hepatic artery thrombosis, which should lead to prompt evaluation with Doppler ultrasonography.

Postoperative pain control is generally achieved with opioids, including patient-controlled analgesia. Analgesic requirements may be decreased compared with other major abdominal surgery.[211,212] Epidural analgesia is contraindicated because of coagulopathy, which usually preexists, or develops during the perioperative period.

The timing of tracheal extubation and termination of postoperative mechanical ventilation is not clear.[213,214] Early extubation of the trachea, including endotracheal tube removal in the operating room, is feasible in select patients. However, the benefits of immediate extubation appear limited to the potential of decreased resource utilization, which might not be fully realized in centers that direct posttransplant patients to ICUs regardless of their need for ventilatory support. As a result, many centers prefer to see clear signs of graft function before extubation.

ACUTE LIVER FAILURE

ALF (previously termed *fulminant hepatic failure*) is defined as the appearance of encephalopathy together with coagulopathy (international normalized ratio [INR] ≥ 1.5) in a patient without previous liver disease who has an illness of less than 26 weeks in duration. ALF is a rare entity with an estimated incidence of approximately 2000 cases per year in the United States and a reported incidence of 1 to 8 per million population in the United Kingdom.[215] Drug-related toxicity, primarily acetaminophen, accounts for the majority of the cases of ALF in the United States and Europe while viral infections are the most common etiologies in many Asian and developing countries.[216] Other causes include idiopathic, autoimmune, and ischemic. Etiology has a significant bearing on outcome; patients with acetaminophen toxicity, ischemic injury, or hepatitis A have the most favorable prognosis, whereas those with non-acetaminophen drug-induced liver injury, acute hepatitis B, Wilson disease, or autoimmune hepatitis have poor prognoses in the absence of transplantation.[217] Outcomes in patients with ALF have significantly improved over the past 40 years due to both transplantation and advances in medical management; over 70% of ALF patients now survive their illness.[218,219] Overall, ALF is a rare indication for liver transplant. In a study of ALF patients listed for transplant in the United States over a 13-year period, only 64% of patients underwent liver transplant. Of those that did not undergo transplant, more than half survived with medical management.[219] In the United States there has been a slight decrease in both waitlist registrations and transplant rates for adult patients with ALF over the last 12 years.[87] In Europe, approximately 7% of liver transplants were performed yearly for ALF.[220] One-year liver transplant survival rates for patients with ALF are between 74% to 84%; both early and late outcomes are generally inferior compared to chronic liver failure patients.[221] There are also significant differences in liver transplant outcomes based on etiology of ALF; outcomes are better in patients with acetaminophen toxicity and acute viral hepatitis compared to other indications.[215] The severity of preexisting multiorgan failure including neurologic involvement in critically ill patients with ALF likely impacts posttransplant outcomes.

Evidence of portal hypertension and cirrhosis is absent in ALF because of the rapid progression of disease. Acute decompensation of chronic liver disease, termed acute-on-chronic liver disease, is a separate condition with different etiologies, therapy, and prognostic indicators. Although various etiologies of ALF exist, there are manifestations that are common to all patients with massive hepatic necrosis. The most serious, and lethal, is acute cerebral edema and intracranial hypertension. Effects on other organ systems include coagulopathy, circulatory dysfunction and hypotension, acute kidney injury, and metabolic derangements.

General measures to reduce cerebral edema include maintaining the patient in a 30-degree, head-up position, and making sure the head is in neutral position so as not to impede venous return. Supportive care includes maintenance of normovolemia, vasopressor therapy for blood pressure support, prevention of sepsis, and intubation for airway protection and control of ventilation. Sedation and muscle relaxants should be considered to minimize increases in ICP from coughing, bucking, and shivering. Mannitol can be used to induce an osmotic diuresis but may have limited utility in the patient with compromised renal function. Early use of renal replacement therapy may be indicated for control of ammonia levels and to optimize electrolyte and acid-base status. Hypertonic saline, ideally targeting a serum sodium of 145 to 155 mEq/L, may be indicated. Current recommendations are to maintain normocarbia and to reserve hyperventilation for response to acute increases in ICP. Barbiturates can be used to decrease cerebral metabolism; however, their use may be limited by hypotension.

Monitoring techniques for cerebral edema and intracranial hypertension are controversial. Serial head computed tomography images are not sensitive indicators of intracranial hypertension. Computed tomography can, however, provide information on structural abnormalities such as intracranial hemorrhage. Although many centers place an ICP monitor to guide therapy in patients with stage III-IV coma, there are no randomized controlled studies to support this practice. Furthermore, ICP monitor placement is not a benign procedure, frequently entailing aggressive correction of coagulopathy and transport to and from the operating room for a critically ill, fragile patient. Nonetheless, ICP monitors are invaluable for guiding acute therapy, and for helping to determine who might no longer be a viable candidate for transplantation. In addition to measuring ICP, these monitors allow calculation of cerebral perfusion pressure (CPP = mean arterial pressure [MAP] − intracranial pressure [ICP]), which should be kept between 50 and 80 mm Hg. An effective protocol for managing intracranial hypertension in patients with stage III or IV encephalopathy has been described and resulted in a 95% response to treatment in episodes of ICP greater than 20 mm Hg. Furthermore, in this prospective series, ICP was monitored in all patients, and no patients died of isolated cerebral edema. The authors used a protocol that included rFVIIa to correct coagulopathy before ICP placement. Significant bleeding complications from ICP monitoring were not encountered.[222]

The decision regarding which patients should receive a transplant, based on who might recover spontaneously or who is unlikely to benefit from transplantation, is one of the most difficult decisions encountered during the management of patients with liver disease. The two most widely used prognostic models are the Clichy or Paul Brousse Hospital criteria and the King's College Hospital criteria. The Clichy criteria recommend transplantation for patients in stage III or IV coma, based on age and factor V levels.[223] There is no distinction made for etiology of ALF, which is considered a weakness of these criteria. The King's College Hospital criteria are superior for predicting outcomes in patients with ALF based on acetaminophen toxicity. However, the negative predictive value is less than 50% in patients who have not used acetaminophen.[224] Thus, patients who fail to fulfill these criteria include a number of patients who will die without proper consideration for transplantation. Recently, dynamic models have been used to predict outcomes in acute ALF patients.[225]

In patients with ALF who are undergoing an invasive procedure, correction of thrombocytopenia to 50,000 platelets/mm^3 or greater and INR to 1.5 or less is suggested.[217,226] Prophylactic therapy may be initiated for severe abnormalities (e.g., platelet count ≤ 10,000/mm^3, INR > 7, and fibrinogen < 100 mg/dL).[217] Viscoelastic testing may be useful for guiding therapy. Use of rFVIIa is reserved for rapid correction in patients who cannot tolerate a large volume of plasma. This agent may carry a thrombotic risk and is contraindicated in hypercoagulable states. The prophylactic use of rFVIIa is generally not recommended unless an invasive procedure is planned.[227] PCC may also have a role in this setting.

Hypotensive patients with ALF should undergo intravascular volume status and cardiac function assessment before consideration of inotropes or vasopressors. MAP should be raised to provide adequate CPP. Vasopressors can be used to treat either systemic hypotension or to maintain an adequate CPP. Based on recommendations for septic patients, norepinephrine should be used. The use of vasopressin is

TABLE 60.3 Pugh's Modification of the Child-Turcotte Classification

	POINTS		
Variable	**1**	**2**	**3**
Encephalopathy	None	1-2	3-4
Ascites	Absent	Slight	Moderate
Prothrombin time (sec prolonged)	<4	4-6	>6
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Bilirubin (mg/dL)	<2	2-3	>3

Child-Pugh class A, 5-6; class B, 7-9; class C, 10-15.

controversial because there is evidence that its use is associated with increases in ICP.[228] However, another study in which terlipressin was used did not reveal similar increases in ICP.[229]

LIVING DONOR LIVER TRANSPLANTATION

See Chapter 61 (Anesthesia for Organ Procurement).

PEDIATRIC LIVER TRANSPLANTATION

See Chapter 77 (Pediatric Anesthesia) and Chapter 78 (Anesthesia for Pediatric Cardiac Surgery).

ORGAN MATCHING AND ALLOCATION

The primary criteria used to match donor liver grafts with recipients are ABO blood type and graft size. ABO-incompatible liver transplantation (ILT) is generally limited to emergent situations, and as many as half of the adult recipients in early reports required retransplantation. Subsequent reports have identified patient populations with more favorable outcomes after ILT. Recipients with blood type O and pediatric patients tolerate ILT better than others.[230] Nonetheless, ILT remains a technique reserved for emergent situations.

In the United States, a national registry maintained by UNOS allocates organs to transplant candidates. In Europe, there are a number of regional or national organ allocation bodies that distribute organs within their respective country or region based on different allocation criteria. UNOS considers only disease severity, and no longer uses waiting time, when allocating deceased-donor liver grafts. Older systems used the Child-Turcotte-Pugh (CTP) score to determine disease severity (Table 60.3). Beginning in 2002, the MELD score replaced the CTP score. The MELD score is a mathematical formula that incorporates the serum bilirubin, creatinine level, and INR. It is considered more objective because there is no reliance on subjective physical examination to determine the presence and severity of findings, such as ascites or encephalopathy. The MELD score is a continuous scale, rather than categorical (found in the CTP score), which provides more discriminatory ability since disparate risks are not grouped within a single category. In addition, the inclusion of the creatinine level (not found in the CTP score) reflects the prognostic importance of renal dysfunction on advanced liver disease. The MELD score is an excellent predictor of 90-day pretransplant (waitlist) mortality (Fig. 60.11).

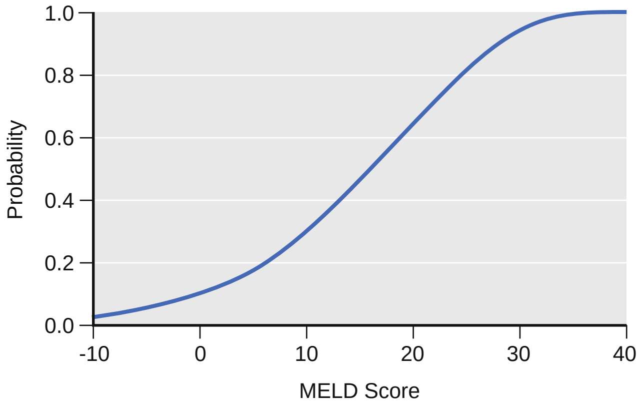

Fig. 60.11 **Relationship between Model for End-Stage Liver Disease *(MELD)* score and 3-month mortality in hospitalized (pretransplant) patients with cirrhosis.** (From Wiesner RH, McDiarmid SV, Kamath PS, et al. MELD and PELD: application of survival models to liver allocation. *Liver Transplant*. 2001;7:567–580.)

The MELD allocation system is regarded as a major advance in liver organ allocation. However, adjustments to the MELD system based on updated information and addition of MELD exception points for specific subsets of patients have been implemented to optimize allocation. For instance, based on observations that hyponatremia is a predictor for mortality in patients with cirrhosis, sodium was added to the calculation for organ allocation (MELD-Na score) in 2016.[231] Hepatocellular carcinoma can progress to inoperable status before manifesting changes in the MELD score, which disadvantages patients with HCC. As a result, UNOS policy grants exception points to patients with HCC to allocate organs equitably to patients with this condition; this exception policy has undergone multiple changes since 2002.[232] Other patient subsets including those with PPHTN, HPS, amyloid, and hilar cholangiocarcinoma also receive MELD exception points. Regional disparities in candidate access to transplantation have been addressed with the Regional Share 35/National Share 15 policy.[233] Candidates with MELD scores less than 15 have better survival without transplantation.[234] However, when the qualities of the donor graft are taken into account using the donor risk index, candidates with MELD scores of 12 to 14 benefit from liver transplant in the event that a favorable (low donor risk index) graft is transplanted.[235]

ANESTHESIA FOR PATIENTS AFTER LIVER TRANSPLANTATION

There are nearly 8000 patients living with liver transplant grafts in the United States; these patients may present for all types of nontransplant surgeries.[87] Liver transplant recipients with functioning grafts typically metabolize drugs in a normal fashion, but graft function must be assessed rather than assumed. The PT (or INR) is an excellent marker of synthetic function. In patients with grafts with impaired synthetic function, clotting abnormalities can be corrected with vitamin K or fresh frozen plasma; ascites managed with diuretics, albumin administration, or paracentesis; and the risk of encephalopathy minimized with lactulose administration and careful use of sedatives.

Careful adherence to sterile technique is required to prevent infectious complications in this immunosuppressed population. A stress dose of corticosteroids is required for patients receiving chronic supplementation. Renal function should be assessed and managed carefully to avoid an exacerbation of immunosuppressant-associated renal impairment. Hypertension is a common finding in patients whose condition is managed with calcineurin inhibitors such as cyclosporine. Drugs known to decrease hepatic blood flow, such as propranolol, should be avoided. Regional anesthesia is an option in patients with acceptable clotting status.

INTESTINAL, LIVER-INTESTINAL, AND MULTIVISCERAL TRANSPLANT

Background

Intestinal, liver-intestinal, and multivisceral transplants have been performed since the mid-1980s, but results were poor until the introduction of tacrolimus and antilymphocyte monoclonal antibodies in the 1990s, which allowed adequate control of rejection. Over the past 2 decades, further refinements in immunosuppression, donor-recipient matching, surgical technique, and perioperative care have steadily improved outcomes. These procedures now have an established role in the treatment of intestinal failure from a wide range of causes. The Intestinal Transplant Registry collected international data from 82 programs transplanting 2699 patients between 1985 and 2013 and reported pooled patient survival of 76%, 56%, and 43% at 1, 5, and 10 years, respectively.[236] Results are continuing to improve, but survival and cost-effectiveness still lag behind those achieved with other organ transplants.[237-239] Intestinal transplantation requires a highly specialized multidisciplinary team who must also provide long-term posttransplant care. Small numbers favor management in regional or national units in which experience is concentrated.

Definitions of intestinal transplant procedures are debated but the most widely used are as follows: Small intestine transplant: intestine without the liver or stomach; liver-intestine transplant: small intestine and liver but no stomach; modified multivisceral transplant: stomach and intestine without liver; multivisceral transplant: intestine plus liver and stomach. The pancreas is often included in a composite graft, usually for technical simplicity but sometimes also to treat pancreatic insufficiency. A segment of colon may also be included.

Indications for intestinal transplant in children include short bowel syndrome from gastroschisis, necrotizing enterocolitis and volvulus, and microvillous inclusion disease. Adults are offered transplantation for thrombotic and traumatic intestinal infarction, desmoid tumor, Crohn-related short bowel syndrome and gut motility disorders. In most of these conditions transplantation has been offered because of life-threatening complications of parenteral nutrition, including progressive cholestasis and liver failure, venous thrombosis leading to loss of two central sites for vascular access, and recurrent catheter-related sepsis. In others, transplant is indicated because of a high risk of death related to the underlying condition, as in congenital mucosal disorders, desmoid tumor, and ultrashort bowel syndrome. In some patients, transplant is considered in the context of frequent debilitating hospitalizations, often for dehydration from stomal losses. While improvements in PN lipid formulations in recent years have significantly reduced PN-associated liver disease, potential new indications have emerged.[239] These include portomesenteric thrombosis in patients with end-stage liver disease, chronic abdominal fistula and sepsis, and patients' unwillingness to accept lifelong PN. Outcome data on these has yet to be reported.

Surgical Procedures

Organs transplanted depend on the indication, recipient liver function, and surgical conditions following previous procedures. Isolated small bowel or small bowel-stomach-duodenum transplant is usual in short bowel syndrome, motility disorders, and desmoid tumor. In this procedure, a donor-to-recipient superior mesenteric artery (SMA) anastomosis supplies arterial inflow; the donor portal vein to recipient IVC or portal vein provides venous outflow (Fig. 60.12).

Liver-intestine transplant, with or without stomach, duodenum, and pancreas, is indicated when PN-related liver disease is significant. Inclusion of pancreas avoids the risk of hilar injury associated with its removal on the back-table and reduces the risk of kinking of adjacent vessels (superior mesenteric vessels, portal vein, middle colonic artery) in the implanted graft. It also avoids the need for Roux loop biliary drainage and is beneficial if the recipient is diabetic. Inflow is typically via aorta-to-SMA anastomosis or conduit, and outflow via donor hepatic veins to IVC or side-to-side anastomosis of donor to recipient retrohepatic IVC (piggyback technique). Pretransplant renal dysfunction from obstructive uropathy, renal vein thrombosis, or recurrent severe dehydration may require implantation of a kidney graft as part of the same procedure.

Once the graft complex is reperfused, a proximal intestinal, gastric, or gastroesophageal anastomosis, is performed for upper gut continuity. This may be followed by end-to-side anastomosis of recipient colon to donor ileum to complete lower gut continuity. The distal end of the transplanted small intestine is then brought out as a temporary stoma. Alternatively, to preserve the recipient ileocecal valve, the donor ileum can be anastomosed to the recipient's distal ileum, which is then used to form the ileostomy. The ileostomy ensures that the graft is not distended postoperatively and allows endoscopic monitoring for rejection. Preservation of the colon is not essential but improves fluid and electrolyte absorption and is naturally preferred by the patient. After completion of the bowel anastomoses, the abdominal wall is closed. This may be difficult, sometimes requiring delayed primary closure, use of reinforcing mesh, a muscle flap, or even grafting of the donor abdominal wall.

Preoperative Assessment

Multivisceral transplant, and to a lesser extent non-liver intestinal transplant, is usually associated with major

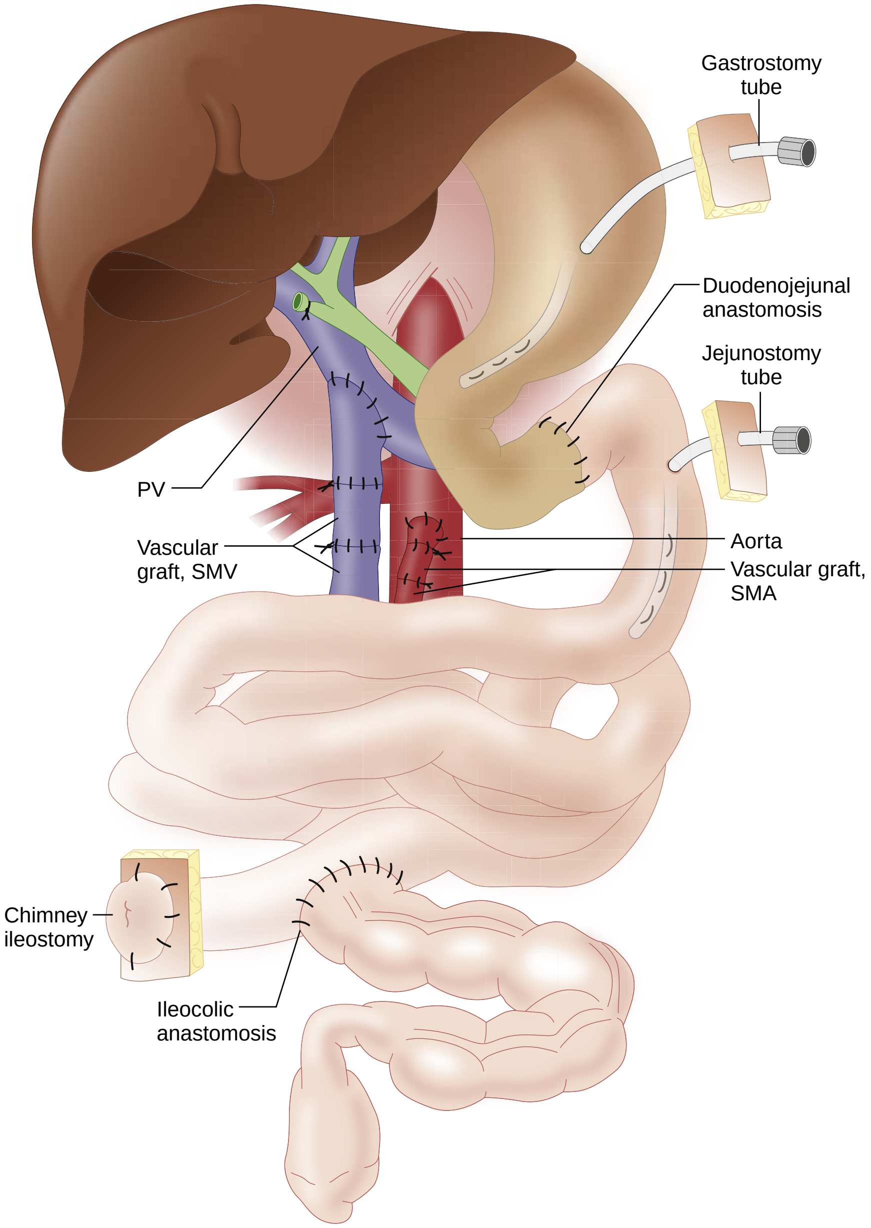

Fig. 60.12 Intestinal transplantation. The implanted donor intestine is illustrated. *PV*, Portal vein; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein. (Modified from Abu-Elmagd K, Fung J, Bueno J, et al. Logistics and technique for procurement of intestinal, pancreatic and hepatic graft from the same donor. *Ann Surg.* 2002;232:680–687.)

operative hemorrhage, hemodynamic instability, electrolyte imbalance, and metabolic acidosis. Adequate nutritional reserve and cardiorespiratory fitness are paramount. Preoperative assessment mirrors that for liver transplant (described earlier) with additional caveats as follows.

Central venous access is often compromised by previous catheter-related infection or thrombosis. Partial or complete obstruction of the innominate veins or superior vena cava is sometimes encountered, even presenting as facial swelling with fluid overload or with exercise, which may contraindicate any graft incorporating a liver. All central vessels must be assessed for patency by ultrasound and, if any doubt, by magnetic resonance angiography. Access above the diaphragm is critical in patients receiving a liver because of the surgical requirement for partial or complete occlusion of the IVC intraoperatively. This is not essential in intestine-only recipients, but patency of both femoral veins must be confirmed. Access should be planned before wait listing, including provision for involvement of an interventional radiologist if necessary.

Coagulation assessment should include rotational TEG and thrombophilia screen. Most multivisceral candidates are prothrombotic on viscoelastic testing, even in the presence of liver dysfunction, and confirmation of this can influence intraoperative management. Chronic abdominal pain associated with opiate use is also present in many intestinal transplant candidates, and specialist pain service assessment and advice are important, since postoperative and longer-term follow-up are often needed.

In candidates with liver disease, PPHTN and HPS should be excluded as routinely done in prospective liver recipients. Given the greater physiological and metabolic demands of a multivisceral procedure compared to liver transplant alone, both of these conditions may contraindicate multivisceral transplant. Important comorbidities include sarcopenia, ischemic heart disease, and diabetes, especially in candidates over 60 years old, and may also indicate prohibitive risk.

Intraoperative Management

To date, literature on the perioperative anesthetic management of intestinal and multivisceral transplant recipients is largely anecdotal. Anesthetic technique, vascular access, and monitoring modalities are mainly as described in the setting of liver transplantation, although the pathophysiological changes of end-stage liver disease are only present in liver-intestine and multivisceral candidates. A description of the differences between liver-intestine and liver-only transplantation follows.[240-242]

Some liver-intestine procedures take 24 hours or longer. Most require the presence of two highly experienced anesthesiologists and specialist ancillary staff, including nurses or technicians to help manage hemofiltration, VVB, cell salvage, rapid infusion devices, and point-of-care testing.

Most recipients have had extensive previous abdominal surgery, so they will have varying degrees of peritoneal sclerosis. Those with portomesenteric venous thrombosis or PN-associated liver disease may also have severe portal hypertension. Dissection and removal of recipient viscera can therefore be prolonged and associated with severe surgical bleeding. In some cases of full multivisceral transplant, on-table angiography and SMA/celiac embolization are performed immediately before surgery to reduce operative hemorrhage. In others, blood loss may be reduced by avoiding left upper quadrant dissection and splenectomy, providing there is enough space for the graft. In all cases, loss of multiple blood volumes should be anticipated. An agreed upon massive transfusion protocol with the hospital blood bank is essential.

Difficult dissection also increases the risk of long ischemia times and harm to the graft. The need to minimize ischemic time requires close coordination between donor and recipient teams, and the recipient anesthetic is started as soon as the organs are judged to be usable, sometimes even before donor explant.

In some transplant centers, in adult patients for liver-intestine transplant with portal hypertension and expected major blood loss, VVB is used from early in the dissection phase to decompress the portal circulation and support cardiac output. This depends on adequate access for femoral and/or portal outflow and internal jugular vein, SCV, or brachial inflow. A heat exchanger is incorporated in the bypass circuit to maintain normothermia during a long period of partial extracorporeal circulation. Since acidosis and hyperkalemia are also common complications in these massively transfused patients, some centers employ preemptive intraoperative hemofiltration, requiring placement of a dual-lumen dialysis catheter in another central vein, ideally separate from any multi-lumen catheter used for vasoactive drugs. Separate cannulae for rapid infusion of blood products and (in adults) a PA catheter are also needed, and one or both may be placed alongside bypass return cannulae and a quadruple-lumen catheter in the right internal jugular vein. Ultrasound guidance during cannulation is indispensable. If right internal jugular vein cannulation is known to be not possible, alternative sites should be planned at the time of assessment. These may involve interventional radiology or surgical access at other supradiaphragmatic sites.

Monitoring for liver-intestine transplant mirrors that in liver transplantation. An added advantage of transesophageal monitoring is the immediate detection of air and thrombus in the heart, both of which are hazards of VVB. The risk of spontaneous thromboembolism, potentially life-threatening, also appears be higher than in liver-alone implantation, given the hypercoagulability often seen on baseline thromboelastogram and unpredictable changes in coagulation during rapid administration of large volumes of blood products. Cell salvage may be used during dissection, but only as long as bowel or bowel fistulae are not breached and the surgical field remains uncontaminated. In practice, this is often brief. However, when hemofiltration is not used, the cell saver may be used to wash bank blood before infusion, reducing the risk of hyperkalemia.

Coagulation is managed as in liver transplantation, guided by the appearance of the surgical field and by TEG. Tranexamic acid is avoided if there is a clinical history of thrombosis or hypercoagulability on TEG. However, if major bleeding supervenes with a clinical coagulopathy and fibrinolysis on TEG, tranexamic acid can be considered. Open communication with a specialist in transfusion medicine is essential. This will help maintain a supportive relationship between blood bank and the transplant team despite exceptional demands on this service, and also facilitates timely use of prothrombin and fibrinogen concentrates when requested.

Reperfusion of an intestine-only graft is typically uneventful, but inclusion of liver in a composite graft usually produces hyperkalemia and at least transient hypotension, since reperfusion involves a large mass of tissue and occurs via hepatic arterial and portal venous routes in close succession. Management is as for liver transplant, with cautious administration of volume and vasopressor as required to maintain MAP. A marked fall in temperature is also seen. Although this is temporary if VVB with a heat exchanger is in use, it can otherwise be slow to correct, especially if continuous venovenous hemodiafiltration is running. Although the latter may be helpful in the prevention of hyperkalemia and severe acidosis, its benefits are unproven. Its use is often interrupted by clot formation in the filter or warming unit, and some consider it a significant distraction in an already complicated environment.

Postoperative Care

Postoperative management involves a variable period of continued mechanical ventilation, and maintenance of intravascular volume, which is diminished by tissue translocation that can persist for 1 to 3 days. Perioperative administration of prophylactic antimicrobials and intensive multi-agent induction of immunosuppression are also essential, as is monitoring of graft perfusion by Doppler ultrasound and stoma endoscopy. Abdominal wall (rectus sheath and subcostal transversus abdominis plane blockade) infusions aid analgesia after extubation, but patient-controlled analgesia is often used at high doses and an ongoing opiate requirement is common. Opiate use often continues beyond discharge despite specialist pain service input and may require long-term psychological support. Postoperative surgical complications are frequent but graft loss is now rare.

Conclusion

Numbers treated in this challenging field are fortunately small, but 20 years of experience is yielding better results, and better outcomes are bringing more and earlier referrals. Further progress will depend on concentrating experience in national or regional centers, and close collaboration among these centers in defining indications and refining clinical care.

POSTABDOMINAL TRANSPLANTATION COMPLICATIONS

Surgical Complications

Early postoperative surgical complications include postoperative bleeding, drainage leaks (bile, urine, pancreatic secretions), and vascular thrombosis. The risk of bleeding and thrombosis is lessened when a balance is maintained between procoagulants and anticoagulants (proteins S and C, antithrombin). Because standard laboratory tests monitor only coagulation, this balance may be difficult to assess in the absence of viscoelastic tests, which evaluate whole blood clotting.

Complications vary based on donor graft qualities and recipient characteristics. For instance, hepatic artery thrombosis is more common in pediatric recipients because of the small caliber of the vessel, and bile leaks are more common after liver transplantation using grafts from cardiac death donors.[243]

Infection

After the immediate postoperative period, infection is the primary cause of death. Immunosuppressive medications, used to prevent rejection, are largely responsible for this risk. Bacterial infections predominate during the early postoperative period. Surgical site infections, intraabdominal abscesses, and infected hematomas are common. In this immunosuppressed population, multidrug-resistant organisms are common. In liver transplant recipients, bacterial translocation or bile leaks can result in peritonitis, cholangitis, and perihepatic abscesses. In one study of liver transplant recipients, 47% of ICU patients had bloodstream infections, 35% had intraabdominal abscesses, and 17% had ventilator-associated pneumonia.[244] Prompt diagnosis and treatment with minimally invasive drainage techniques should be considered over early laparotomy. When this approach fails, laparotomy is indicated.

Prolonged endotracheal intubation and indwelling central venous and urinary catheters are a common source of infection. These devices should be removed as early as possible in the postoperative period. In the meantime, strict aseptic technique is required when accessing indwelling catheters and tubes.

Comorbidities, such as diabetes and renal dysfunction, can increase the risk of infection. Viral and fungal infections are more likely after the first postoperative week. Risk factors for fungal infection in liver transplant patients include preexisting viral hepatitis, diabetes mellitus, multiple organ system failure, prolonged parenteral nutrition, long-term mechanical ventilation, and increased antibiotic use.[245] Common sites of fungal infection include oral, esophageal, pulmonary, and intracerebral. Invasive fungal infections, despite prolonged treatment with amphotericin or itraconazole, are associated with a poor prognosis.

Immunosuppression

Acute cellular rejection (ACR) is an important cause of graft dysfunction within the first year of transplant. ACR rates have decreased with improvements in immunosuppression; ACR occurs in 15% to 25% of liver transplant patients and in less than 10% of kidney recipients.[10,246] Generally, ACR responds well to therapy, however, chronic rejection is a significant cause of graft loss for all organs. The goals of immunosuppression are to prevent graft loss and to avoid the adverse consequences of antirejection regimens.[247] Immunosuppression for solid organ transplant is divided into initial (induction) and maintenance phases. Calcineurin inhibitors cyclosporine and tacrolimus (formerly FK506) are the foundation for the majority of induction and maintenance regimens. Both agents inhibit transcription of interleukin (IL)-2 and other cytokines, primarily in helper T lymphocytes. Both manifest renal toxicity, which is caused by afferent arteriolar vasoconstriction and a reduction in GFR. The resulting azotemia is reversible with a reduction of dosage. Hypertension is due to vasoconstriction and sodium retention, and typically appears within the first weeks of treatment. Neurologic toxicity includes tremors, headaches, seizures, and even focal neurologic abnormalities. Mycophenolate mofetil therapy is a beneficial adjunct by allowing a reduction in the doses of calcineurin inhibitors.

In addition to tacrolimus, the most widely used drug, there are many other drugs available.[248] Sirolimus, an inhibitor of the protein mTOR, is used for calcineurin-sparing effects and in patients transplanted for hepatocellular carcinoma to reduce recurrence.[249] Basiliximab, a monoclonal antibody to CD25, has been used as an alternative to steroids for the induction of immunosuppression in liver transplantation.[250]

New immunosuppressive drugs are typically introduced for use in renal transplantation before they are applied in liver transplantation. Of note, recipients of liver grafts require less immunosuppression than do recipients of other organs, and liver grafts confer protection on other organs transplanted from the same donor. This effect is an example of the privileged immune status of the liver.[247]

The diagnosis of rejection requires a biopsy. The threshold for performing a biopsy should be low, albeit with an awareness that other conditions can mimic the histologic changes seen with rejection. For instance, diffuse lymphocytic infiltration of the kidney can be seen with rejection or lymphoproliferative disorder, and recurrent hepatitis C in the liver can resemble rejection.

Malignancy

Immunosuppressant drugs increase the susceptibility of transplant recipients to malignancy.[251] This effect is primarily related to the level of immunosuppression, but production of transforming growth factor-β may also be responsible. The spectrum of malignancy is wide ranging and includes cancers seen with HIV-infection, a condition also associated with immunosuppression. Lymphoma regression occurs if the immunosuppressive agent is discontinued early.

In a retrospective study of more than 250,000 solid organ transplant recipients, Hodgkin lymphoma risk factors included male sex, young age, and Epstein-Barr virus (EBV) seronegativity at the time of transplant.[252] In a study of 175,000 solid organ recipients (primarily kidney and liver recipients), malignancy was identified in more than 10,000 patients, a standardized incidence ratio (SIR) of greater than 2 compared with the general population.[253] The cancer sites with the highest relative risk included Kaposi sarcoma (SIR = 61), lip (SIR = 17), skin, nonmelanoma (SIR = 14), liver (SIR = 12), vulva (SIR = 8), and non-Hodgkin lymphoma (SIR = 8).

Posttransplant lymphoproliferative disorder (PTLD) is associated with a proliferation of B cells after transplantation in response to infection with EBV. Clinical presentation varies from a mononucleosis-like syndrome to malignant lymphoma. Pediatric patients are at increased risk due to a lower likelihood of prior exposure to EBV. Diagnosis is made by biopsy of the affected area, which can include the graft. Treatment consists of a reduction of immunosuppression levels and antiviral therapy against EBV, primarily ganciclovir. Individuals at high risk, such as patients who are seronegative for EBV or who receive a graft from a seropositive donor, should be maintained on antiviral prophylaxis.

The mean latency period for all cancers is 3 to 5 years after transplant, although specific malignancies exhibited unique time intervals. Cancer sites vary depending on the organ transplanted; for example, renal transplant recipients have a 100-fold greater than expected risk of developing carcinoma in the native kidney.[254] The reasons are unclear, but prolonged dialysis before transplantation may be a risk factor.[255] The use of specific immunosuppressive drugs also affects the relative risk of various cancers. For example, OKT3, which contains antibodies directed against T lymphocytes, is associated with an increased incidence of PTLD. Antibodies directed against B lymphocytes (rituximab) can reduce the incidence of PTLD. Sirolimus is not associated with cancer risk, and in fact may have antitumor effects.

Long-Term Survival

Long-term survival is affected by common diseases such as hypertension, hyperlipidemia, and diabetes mellitus.[256] The leading long-term causes of death after liver transplant are hepatic processes (disease recurrence or organ rejection), malignancy, and cardiovascular disease.[257]

Conclusions

Abdominal organ transplantation has matured over the past 50 years. From its beginning as an experimental procedure, it has become the best hope for survival in the case of liver transplantation, and the best option for an independent life without morbidity in the case of renal and pancreatic transplantation. Challenges for the future include a solution to the organ shortage, methods to minimize the likelihood of disease recurrence, and pharmacologic advances aimed at limiting the side effects of immunosuppression.

61 Anesthesia for Organ Procurement

VICTOR W. XIA and RANDOLPH H. STEADMAN

KEY POINTS

- The shortage of organs available for transplantation is a worldwide problem.
- The discrepancy between the number of patients waiting for organ transplantation and the available organs remains significant, but has narrowed since 2013.
- Most organs in the United States are donated after neurologic death, with a small portion donated after circulatory death and from living organ donors.
- Neurologic-death donors have physiologic alterations that must be actively managed to ensure that the organs are suitable for transplantation.
- Determining neurologic death and circulatory death should follow national guidelines and local institutional protocols.
- The anesthesiologist must have an awareness of the ethical and legal issues related to the declaration of death that precedes organ donation.
- Expansion of the donor pool through the inclusion of extended criteria, such as high-risk donors, addresses the organ shortage and decreases waiting-list mortality.
- The use of extended criteria high-risk organs significantly impacts recipient outcomes and presents challenges to perioperative management.
- Ischemia-reperfusion injury in organ transplantation is unavoidable; however, management strategies can lessen the likelihood of postoperative graft failure.
- Goal-directed donor management can improve the number of organs transplanted per donor.
- Living organ donor kidney transplantation remains an important donor source in the United States, whereas the use of living donors for liver transplantation varies by country.
- New technologies, including machine perfusion after procurement, are promising as a means to mitigate the effects of prolonged preservation time, to increase the donor pool, and to improve transplant recipient outcomes.

Introduction

Organ transplantation requires the donation and successful procurement of a human organ. The success of organ transplantation relies on a functioning donor graft. The majority of organs used for transplantation in the United States are from donors after the declaration of neurologic death (donation after neurologic death, DND). Organs from donation after circulatory (cardiac) death (DCD) and living organ donation are in the minority, however, they remain an important source of donors.[1] Organs procured from these sources have different characteristics and present varying challenges in management. For instance, DND donors often have significant physiologic alterations and hemodynamic instability that is associated with neurologic death. These alterations and instability, if not treated, will lead to organ deterioration and may prevent the organ from being suitable for transplantation. In contrast, DCD donors have an obligatory period of hypotension of varying duration before cardiac arrest. The resulting compromise in perfusion can exacerbate reperfusion injury and lead to an increased incidence of posttransplant biliary dysfunction.

The shortage of organs is a worldwide problem and is the most important obstacle in organ transplantation. The gap between the number of patients waiting for transplant and the available organs has widened (Fig. 61.1). In 2015, more than 119,000 transplant candidates were wait-listed in the United States through the United Network for Organ Sharing. Of these, 33,000 candidates underwent transplant surgery.[2] The majority of candidates were awaiting kidney grafts, with a smaller number awaiting liver, heart, and lung grafts. Many strategies were implemented to decrease the gap between the demand and supply, including public awareness campaigns and updates to the organ allocation system. Organ donation rates and the number of organs transplanted per donor vary substantially across geographic regions. Per 100 eligible deaths in the United States in 2016, the organ donation rate was 72.3, ranging from 52.9 to a high of 93.3 (Israni OPTN 2016 Annual Data Report).[3] To increase the number of organs for transplant, many programs have expanded the donor pool by using extended criteria donors (ECDs). Not surprisingly, the number of organs transplanted per donor varies according to donor category: ECD, DCD, or standard criteria donor (SCD). The number of organs transplanted from DCD donors is similar to ECDs, primarily attributable to the ability of the kidney to tolerate the longer periods of ischemia associated with organ procurement after DCD. The use of

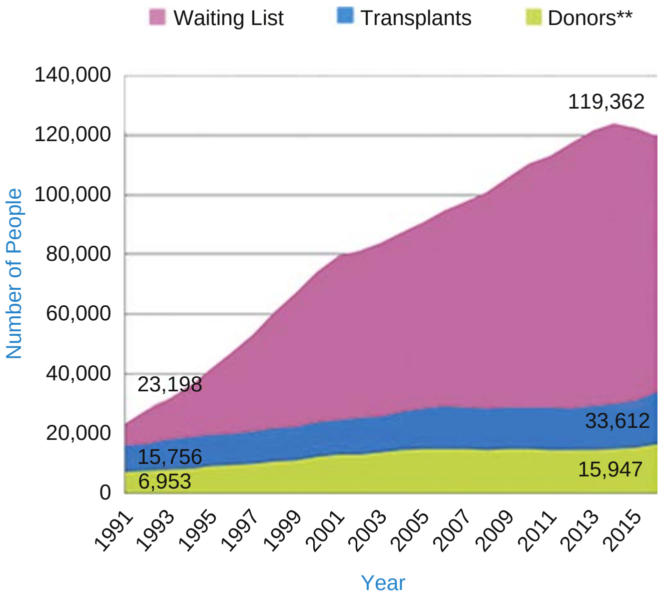

Fig. 61.1 The gap in the United States between the number of donors, patients transplanted, and patients on the waitlist by year, 1991 to 2015. The gap has declined since 2013. **Donors can be deceased and living. http://www.organdonor.gov/statistics-stories/statistics.html.

living-related and living-unrelated donors is widespread in countries with moral or legal objections to neurologic death and is an important worldwide donor source. Many policies have been proposed to promote the best practices in organ donation.[3,4] There are several areas that have the potential to expand the donor pool, which include deaths that are not referred to the organ sharing agencies and organs that have been procured, but unused for transplant.

Organ transplantation is a complex process that requires close coordination among many specialized teams. Procurement organizations, transplant coordinators, social workers, nurses, surgeons, internists, intensivists, and anesthesiologists are involved in the process. To maximize the number of organs transplanted and to preserve the best possible function of donated organs, anesthesiologists need to understand the pathophysiologic derangements associated with donation and ischemia-reperfusion injury. In addition, anesthesiologists must be aware of the ethical and legal issues related to the declaration of death and organ donation.

Management of Organ Donors After Declaration of Neurologic Death

DND (also called after declaration of brain death) provides the majority of donated organs in the United States.[3] Organ procurement from DND donors can only occur after the declaration of death. The concept of neurologic death emerged in the 1950s. In 1968, a Harvard Ad Hoc Committee on Irreversible Coma established a set of criteria that has been widely used for the determination of neurologic death.[5] In the United States, the Uniform Determination of Death Act was approved in 1981 by the National Conference of Commissioners on Uniform State Laws, in cooperation with the American Medical Association, the American Bar Association, and the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research. Although the criteria for the declaration of neurologic death were based on ethical principles established several decades ago, the criteria remain valid today.[6]

Although the concept of neurologic death has been widely accepted in Western cultures, minor variations in definition and implementation exist in different countries. Despite these differences, the clinical criteria are similar.[7] A larger difference exists among different cultures in accepting and implementing the neurologic death criteria. In fact, neurologic death has not reached a legal status in some countries, such as China.

TABLE 61.1 Pathophysiologic Changes Associated With Neurologic Death

Signs and Symptoms	Pathophysiologic Changes	Incidence (%)
Hypertension	Catecholamine storm	80-90
Hypotension	Vasoplegia, hypovolemia, reduced coronary blood flow, myocardial dysfunction	80-90
Bradycardia and other arrhythmias	Catecholamine storm, myocardial damage, reduced coronary blood flow	25-30
Pulmonary edema	Acute blood volume diversion, capillary damage	10-20
Diabetes insipidus	Posterior pituitary damage	45-80
Disseminated intravascular coagulation	Tissue factor release, coagulopathy	30-55
Hypothermia	Hypothalamic damage, reduced metabolic rate, vasodilation, and heat loss	Varied
Hyperglycemia	Decreased insulin concentration, increased insulin resistance	Common

PATHOPHYSIOLOGIC CHANGES WITH NEUROLOGIC DEATH

A variety of pathophysiologic changes are associated with neurologic death. The pathophysiologic mechanisms of neurologic death have profound effects at the molecular, cellular, and tissue levels. The clinical presentations associated with neurologic death may be complex and vary from patient to patient. They can be further complicated by prior pathologic abnormalities, disease, and therapy. The typical pathophysiologic changes associated with neurologic death are further described in Table 61.1.

CARDIOVASCULAR RESPONSES TO NEUROLOGIC DEATH

The cardiovascular system is closely regulated by the central neural system. Cardiovascular responses to neurologic death usually consist of two phases. The first phase is characterized by sympathetic discharge (catecholamine storm), which causes intense vasoconstriction or elevated systemic vascular resistance (hypertensive crisis), tachycardia, and a redistribution of blood volume with visceral ischemia. Acute myocardial injury can occur in neurologic-dead donors without a history of coronary artery disease.[8] Echocardiographic evidence of myocardial dysfunction is observed in 40% of neurologic-dead donors under consideration for heart donation.[9] At times, parasympathetic activation can result in bradycardia. After the sympathetic discharge of the first phase, the loss of sympathetic tone, decreased cardiac output, blunted hemostatic responses, and severe peripheral vasodilatation (vasoplegia) characterize the second phase. In addition to neurohormonal disturbances, other contributing factors include blood loss, intravascular depletion attributable to capillary leakage, osmotic therapy for rising intracranial pressure (ICP), and diabetes insipidus.

The first phase is correlated with ischemia in various parts of the brain and is attributable to an increase of ICP, and the second phase is caused by cerebral herniation and spinal cord ischemia. Although the first hypertensive phase generally represents a transient period in the progression to neurologic death, the second hypotensive phase is profound and sustained. Failure to correct these cardiovascular derangements results in poor organ perfusion and inadequate tissue oxygenation, which will threaten the viability of the donated organs.

RESPIRATORY RESPONSES TO NEUROLOGIC DEATH

An increase in systemic vascular resistance after neurologic death results in blood shifting from the systemic circulation to the more compliant pulmonary circulation. The resulting increase in hydrostatic pressure in the pulmonary circulation causes pulmonary capillary leakage and pulmonary edema. Sympathetic activity triggers a sterile systemic inflammatory response, initiating infiltration of neutrophils and increasing pulmonary endothelial permeability, which further contributes to lung injury. Proinflammatory cytokines are released at the alveoli and are associated with early graft failure and mortality after lung transplantation. The inflammatory response in neurologic-dead donors is associated with the deterioration in cardiac function and a shift to anaerobic metabolism. Hormonal instability can reduce alveolar fluid clearance, resulting in significant accumulation of extravascular lung water. If ventilation is not supported, then respiratory arrhythmia progresses to apnea and cardiac arrest.[10,11]

ENDOCRINE, METABOLIC, AND STRESS RESPONSES TO NEUROLOGIC DEATH

Neurologic death is frequently associated with pituitary failure and disturbances of cortisol, thyroid hormones, antidiuretic hormone, and insulin. Posterior pituitary function in neurologic-dead donors is frequently lost. The development of central diabetes insipidus results in severe fluid and electrolyte derangements and can be observed in up to 90% of neurologic-dead donors.[10] Anterior pituitary function in neurologic death can also be affected, resulting in a deficiency in triiodothyronine (T_3) and thyroxine (T_4), adrenocorticotropic hormone, thyroid-stimulating hormone, and human growth hormone. Thyroid hormonal deficiency may be similar to the euthyroid sick syndrome commonly observed in the non-neurologic injured patient with multisystem organ failure. Hyperglycemia is commonly encountered in neurologic-dead donors because of decreased insulin concentrations and increased insulin resistance. Hypothalamic function and control of body temperature are lost. Although hyperpyrexia may initially occur, hypothermia follows, which is caused by a reduction in metabolic rate and muscle activity, in combination with peripheral vasodilation. Disseminated intravascular coagulation is present in up to one-third of isolated patients with head injuries and is believed to be caused by the release of tissue thromboplastin from brain tissue.[11]

Donation After Circulatory (Cardiac) Death

Before the acceptance of neurologic death, all organs procured were from donors who suffered a cardiac demise (DCD, previously known as donation from a non–heart-beating donor). After the establishment of the Harvard criteria for neurologic death, DND quickly became the principal source of organ donation. However, an interest in the use of DCD organs has been renewed in recent years, driven by the persistent shortage of DND donors and the lack of acceptance of neurologic death in some countries. Policies and protocols developed by healthcare organizations now encourage DCD organs, and their use is increasing in the United States and other countries. In the United States, the number of DCD donors continues to increase, and accounted for over 17% of donors in 2016 (Fig. 61.2).[3] During the same period, the number of living donors dropped slightly from 7000 to 6600. Kidney grafts accounted for over 95% of the organs transplanted from living donors during this period. The American Society of Anesthesiologists established a Sample Policy for Organ Donation after Circulatory Death, with the recommendation that its members actively participate in the development of institutional DCD protocols.

DCD donors are divided into five categories: I, patients who are dead on arrival at the hospital; II, unsuccessfully resuscitated patients; III, patients in whom cardiac arrest is imminent; IV, cardiac arrest in neurologic-dead donors; V, unexpected arrest in the intensive care unit (ICU). Categories III and IV are considered as controlled DCDs, whereas the remaining categories are considered uncontrolled DCDs. Controlled DCD implies that life-support withdrawal can be planned and the transplant team is awaiting the cardiac arrest and is ready for rapid organ recovery. In contrast, uncontrolled DCD implies the patient has experienced an unanticipated cardiac arrest, and organ donation is considered only after an unsuccessful resuscitation. Warm ischemia time is significantly longer in uncontrolled DCDs. Currently, most DCD donors for organ transplantation are controlled DCD donors. Successful use of the uncontrolled DCD grafts has been reported in several studies.[12]

DCD donors usually suffer from irreversible brain or spinal injury but do not meet the neurologic death criteria. The prognosis for a meaningful quality of life is poor. Withdrawal of therapy must be based on a clinical decision of

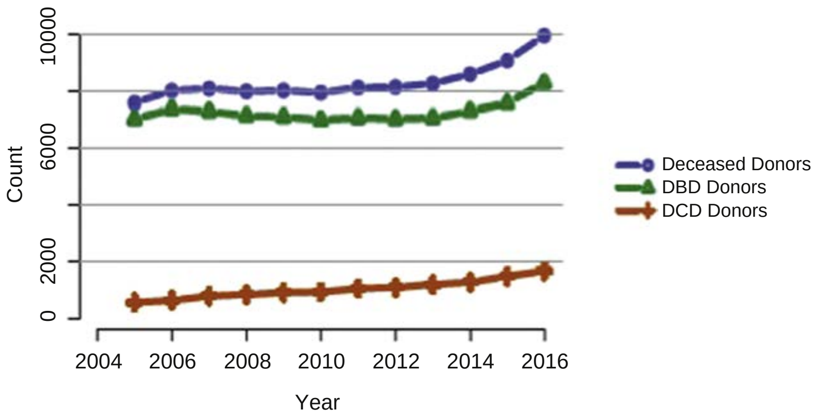

Fig. 61.2 Total number of organ donors in the United States by year, 2005 to 2016. *DBD*, Donation after brain death; *DCD*, donation after cardiac death. (Redrawn from Israni AK, Zaun D, Rosendale JD, et al. OPTN / SRTR 2016 Annual Data Report: Deceased organ donation. *Am J Transplant.* 2018;18:434–463.)

futility and conform to the wishes of the patient and family. The consideration of the withdrawal of life-sustaining therapies must be independent from any discussion related to transplantation. The transplantation team cannot be involved in this decision. Drugs can be used to relieve pain and anxiety and to provide comfort for the patient during withdrawal. Therapies designed to improve graft quality, but without benefit to the patient, are controversial; however, therapies with minimal impact on the patient that improve organ survival are allowed in some protocols.

Declaration of circulatory death should follow procedures proposed by national organizations and policies adopted by the local institution.[13,14] After a decision has been made to withdraw support, the trachea is extubated and life support is stopped. A physician who is not involved with organ transplantation declares cessation of cardiac function. Declaration of circulatory death is not different from clinical practice, which requires a clinical examination to confirm pulselessness or the absence of an arterial waveform. The duration between cessation of cardiovascular activities and the declaration of circulatory death is usually 2 to 5 minutes to ensure irreversibility. Organ procurement starts after death is declared.

Although organs procured from DCD donors are not exposed to the physiologic derangements of neurologic death, they are at greater risk for ischemia-reperfusion injury than organs from DND donors. This results from hypoxemia and ischemia in a warm environment, which is unique during DCD procurement. The time elapsed from extubation to circulatory death is an important factor for determining the suitability of organ donation. If spontaneous breathing and/or heart function continues for a prolonged period after life support withdrawal, then the organs may not be suitable for transplantation, particularly in donors with comorbidities. To assist physicians in predicting how long a patient will sustain life after the withdrawal of life support, a 6-variable score was developed by the University of Wisconsin (UW) (Table 61.2). A low score (8-12) means that breathing and/or cardiac function will continue for some time. A high score (19-24) means that apnea and cardiac arrest are imminent.[15]

TABLE 61.2 University of Wisconsin Criteria for Donation After Circulatory Death: An Evaluation Tool

Variables	Points
SPONTANEOUS RESPIRATION AFTER 10 MIN	
Respiratory rate > 12 breaths/min	1
Respiratory rate < 12 breaths/min	3
Tidal volume > 200 mL	1
Tidal volume < 200 mL	3
Negative inspiratory force > 20 cm H_2O	1
Negative inspiratory force < 20 cm H_2O	3
No spontaneous respiration	9
BODY MASS INDEX (KG/M^2)	
<25	1
25-29	2
≥30	3
VASOPRESSORS	
None	1
1 pressor	2
≥2 pressors	3
PATIENT AGE (YEARS)	
0-30	1
31-50	2
>50	3
INTUBATION	
Endotracheal tube	3
Tracheostomy	1
OXYGENATION AFTER 10 MIN	
O_2 saturation > 90%	1
O_2 saturation 80%-90%	2
O_2 saturation < 80%	3

University of Wisconsin score: 8-12, high probability; 13-18, moderate probability; and 19-24, low probability for continuing to breathe after extubation.
(From Lewis J, Peltier J, Nelson H, et al. Development of the University of Wisconsin Donation After Circulatory Death Evaluation Tool. *Prog Transplant.* 2003;13:265–273.)

The two separate definitions and procedures used for DND and DCD have led to a new debate about the definition and determination of death. A uniform concept of death, which combines all previous criteria for death, is emerging. A growing consensus is that all criteria used to diagnose human death rely on the demonstration of the irreversible loss of the capacity to breath, combined with the irreversible loss of the capacity for consciousness. The irreversible loss of these two functions equates to human death.[16]

Category III (impending cardiac arrest) DCD is the ideal source for organ transplant. Kidneys from DCD donors are frequently used. Several studies have shown that, despite a higher incidence of delayed graft function (DGF), kidneys from DCD donors have comparable short- and long-term graft survival.[12] Livers from DCD donors have a higher likelihood of postoperative biliary complications such as diffuse ischemic cholangiopathy with intrahepatic biliary stricture and may also have a higher incidence of primary graft nonfunction and DGF compared to grafts from DND donors.[17] Ischemic cholangiopathy occurs more frequently if the donor is older, is overweight, and has a prolonged ischemic period. Heart and lungs are susceptible to ischemia and only a few cases of the successful use of such grafts from DCD donors have been reported.[15]

Extended Criteria Donor

Traditionally, DND organ donors are young and otherwise healthy until stricken by an isolated cerebral event or head injury (SCDs). As the numbers of patients waiting for transplant increase, many centers have extended donor criteria to minimize waiting-list mortality. Many terms, including suboptimal donor, marginal donor, inferior donor, nonstandard donor, and high-risk donor, have been used.[18] The criteria that make up the ECD group are more elusive and evolving. Donor characteristics of ECDs vary from organ to organ but generally include advanced age, prolonged cold ischemia time, inferior organ function, and other comorbidities.[18,19] However, donor risk is a relative term and should be described as a continuum, not a dichotomy of SCD and ECD. Therefore, donor risk index (DRI) has been developed for donors.

The kidney DRI has been developed using 10 donor characteristics (Box 61.1).[20] The kidney DRI can be converted into the kidney donor profile index (scale 1%-100%). A higher kidney donor profile index indicates a higher graft failure rate. The DRI has been defined for liver grafts. DRI is a quantitative assessment of the risk of graft failure associated with the donor. Liver DRI is calculated from eight donor characteristics (Box 61.2).[21] Despite an increased risk of graft failure, moderate-to-high acuity transplant candidates who receive a high DRI graft have a survival benefit compared with those remaining on the wait list.[22] Calculation of the DRI can help physicians make a decision to accept or reject a donor offer; however, the calculation requires a projected cold ischemia time.

The use of ECD or high-risk DRI grafts has implications on intraoperative management. In a study of liver transplantation, several donor characteristics are associated with a high incidence of intraoperative hyperkalemia in adults: DCD grafts, prolonged ischemia time, and prolonged donor hospital stay before procurements.[23] ECD liver grafts are also associated with postreperfusion syndrome, intraoperative bleeding, and postoperative reoperation.[24]

Management of Organ Donors Before Procurement

As previously discussed, various physiologic derangements are common in DND donors. If not treated, these derangements can lead to graft deterioration, resulting in organs unsuitable for transplantation. A discussion of treatment strategies follows.

BOX 61.1 Kidney Donor Profile Index

The following donor characteristics are used to calculate the kidney donor profile index
Age
Height
Weight
Ethnicity
History of hypertension
History of diabetes
Cause of death
Serum creatinine
Hepatitis C Virus status
Donation after circulatory death status

From https://optn.transplant.hrsa.gov/resources/allocation-calculators/kdpi-calculator.

BOX 61.2 Liver Donor Risk Index

Age (four categories): >40, >50, >60, >70 years
Cause of death (two categories): cerebrovascular accident (lower risk) versus other
Race: African American (higher risk) versus other
Donation after circulatory death: yes or no
Partial or split graft: yes or no
Height: increasing risk as height decreases below 170 cm
Regional or national share: yes or no
Cold ischemia time

CARDIOVASCULAR MANAGEMENT

Although both hypertension and hypotension are associated with neurologic death and can result in poor perfusion to the organs, hypotension is more profound and difficult to treat. Maintaining adequate intravascular volume is probably the most effective therapy for vasoplegia. No evidence demonstrates that a specific crystalloid solution is superior to another. Adequate resuscitation, as evidenced by a mean arterial pressure of 60 to 100 mm Hg, may decrease cytokine levels and increase the number of organs available for transplantation.[25] Large doses of starch-based colloids should be avoided because they may be associated with DGF.[26]

When hemodynamic stabilization is not achieved with fluid resuscitation, vasoactive drugs should be considered. Dopamine is most commonly used in this setting. If a large dose of dopamine is required, then a second vasoactive agent can be added. Dopamine and other catecholamines have beneficial antiinflammatory and immunomodulatory effects. Vasopressin is recommended as the initial therapy of choice for potential heart donors by the American College of Cardiology.[27] Vasopressin reduces catecholamine requirements and is an effective treatment for diabetes insipidus.

For a potential heart donor, cardiac function should be assessed, with early interventions to improve the donor procurement rate. Echocardiography is useful since it can identify both functional and structural abnormalities. Functional abnormalities identified in the early stage can be managed before heart transplantation, whereas structural abnormalities may preclude transplantation. Coronary angiography is useful in older donors with suspected or known coronary artery disease. Myocardial damage caused by catecholamine storm may be prevented or attenuated by controlling cardiovascular responses, which may increase the number of heart transplants.[11] However, large doses of norepinephrine are associated with increased cardiac graft dysfunction and increased recipient mortality.[28]

Excessive intravascular fluid therapy may have detrimental effects and should be avoided in lung donors. Fluid restriction increases the number of lung grafts available for transplantation.[10] Because this practice creates a conflict of interest on the basis of which organs will be procured, particularly between the lungs and kidneys, fluid management should be balanced to optimize overall donation potential.[10] The goal is to maintain a euvolemic state and to maintain arterial blood pressure and cardiac output with the least amount of vasoactive support possible. Invasive hemodynamic monitoring may be used to guide intravascular fluid therapy.

PULMONARY MANAGEMENT

The lungs are vulnerable to injury and, consequently, are one of the most difficult organs to preserve. Only 15% to 25% of donated lungs are used in transplantation. Current pulmonary management for potential lung donors favors small tidal volume ventilation. The focus of pulmonary management is to recruit and retain lung units while limiting tidal volume and inspiratory pressure. This strategy is extrapolated from studies in acute respiratory distress syndrome. Specific approaches to ventilator management for the donor are variable, but a common approach is a low tidal volume (6-8 mL/kg), low fraction of inspired oxygen concentration (FiO_2), and relatively high positive end-expiratory pressure (PEEP).[29] Pulmonary recruitment maneuvers, using pressure-controlled ventilation and high PEEP (15 cm water), followed by a return to conventional volume-controlled ventilation with a lower PEEP, are recommended by others. The administration of aerosolized terbutaline increases alveolar fluid clearance via β-adrenergic stimulation.[30] As previously discussed, a large amount of intravascular fluid and/or large-dose vasopressors are associated with impaired graft function in potential lung donors.[10]

Adequate gas exchange and good oxygenation are the most important indicators of the functional quality of the lung. However, an initial PaO_2/FiO_2 ratio less than 300 mm Hg should not be used as grounds for exclusion. Reversible processes such as secretions, pulmonary edema, and atelectasis can affect the PaO_2/FiO_2 ratio. Bronchoscopy is generally performed to remove mucous plugs that are present.

TEMPERATURE

Since hypothalamic function and regulation of body temperature are lost, DND donors usually have initial hyperpyrexia followed by hypothermia. Donor hypothermia is also contributed by reduced metabolic rate and peripheral vasodilatation. Normothermia has been traditionally recommended before and during procurement by using active warming devices. A recent report from a prospective trial challenges this traditional temperature management before procurement. In this trial, organ donors were randomized into two targeted temperature groups: mild hypothermia (34°C-35°C) or normothermia (36.5°C-37.5°C). The hypothermia group is associated with a significantly lower rate of DGF after kidney transplantation.[31] In a retrospective study, mild hypothermia is confirmed to reduce DGF, but not graft survival in kidney transplantation.[32]

HORMONES, STEROIDS, ELECTROLYTES, AND GLYCEMIC CONTROL

Hormonal deficiency is common in neurologic-dead donors and hormonal replacement is beneficial.[8,10] Exogenous replacement of antidiuretic hormone in neurologic-dead donors improves graft function in kidney, liver, and cardiac recipients.[10] Thyroid hormone replacement improves the number of organs transplanted per donor and cardiac recipient survival.[25,33] However, most studies showing advantages to hormone supplement are retrospective; adequately powered randomized trials are lacking.

The systemic inflammatory response associated with neurologic death leads to pulmonary infiltration of neutrophils and the elevation of interleukins. The systemic inflammatory response of the donor is associated with graft failure and recipient mortality. Methylprednisolone administration can moderate the inflammatory response and may improve oxygenation, reduce lung water, and increase lung yield. Methylprednisolone administration can also decrease inflammation in the liver, heart, and kidney.

Intravascular volume replacement is essential in the donor management. An isotonic crystalloid (lactated Ringer solution or 0.9% saline) is the preferred choice. However, 0.9% saline may not be the best choice due to the development of hyperchloremic metabolic acidosis. Colloid solutions are appropriate for rapid intravascular volume expansion. Routine use of hydroxyethyl starch is not recommended since it is associated with potential acute kidney injury, and coagulopathy. After administering initial fluid to correct hypovolemia, hypernatremia should be treated by giving a hypotonic solution.[10] Studies have demonstrated that donor hypernatremia (>155 mmol/L) is associated with poor post–liver transplant outcomes.[34] Analysis of heart donors in Europe showed increased recipient mortality when donor sodium was less than 130 or greater than 170 mmol/L.[35] Correction of severe hypernatremia before organ procurement appears to attenuate post–transplant liver dysfunction.[10] Hyperglycemia in the donor is common and exacerbated by steroid therapy. Poor glucose control adversely affects donor renal function.[36] Insulin management should target a glucose level between 120 and 180 mg/dL. Routine use of IV fluid containing dextrose is not recommended.[33]

DONOR MANAGEMENT GOALS

Current recommendations stress the use of standardized donor management with specific preprocurement goals. The objective of donor management goals (DMGs) is to maintain cardiovascular, pulmonary, renal, and endocrine homeostasis. The primary hemodynamic goal is to maximize perfusion for organ preservation by ensuring adequate intravascular volume and cardiac output.[33] Table 61.3 summarizes common goals reported by various

TABLE 61.3 Donor Management Goals, as Reported by Various Authors

Preset Clinical End Points	Six DMGs[*]	Eight DMGs[†]	Ten DMGs[‡]
Mean arterial pressure (mm Hg)	≥60	60–120	60–100
Central venous pressure (mm Hg)	≤10 (or serum osmolality 285-295 mmol/L)	4–12	4–10
Final sodium (mmol/L)	≤155	≤155	135–160
Pressors	≤1 (1 plus vasopressin to treat DI is acceptable)	≤1 or low dose	≤1 and low dose
PaO_2 (mm Hg) or PaO_2/FiO_2 ratio	$PaO_2 \geq 300$ while on 100% oxygen (or $PaCO_2/FiO_2$ ratio > 3)	Final $PaO_2 > 100$	PaO_2/FiO_2 ratio: >300 on PEEP = 5 cm H_2O
Arterial blood gas: pH	7.25–7.50	7.30–7.50	7.30–7.45
Glucose (mg/dL)		≤150	<150
Urine output (mL/kg/h) in 4 h before procurement		0.5–3.0	1–3
Ejection fraction of left ventricle			>50%
Hemoglobin (mg/dL)			>10

studies and recommended by some committees. Studies have shown that compliance with predetermined goals significantly improves the number of organs procured and transplanted.[25,37] Early achievement of DMGs is important. Donors with four or more organs transplanted per donor have significantly more individual DMGs met at the time of consent. Efforts should focus on early management in patients with catastrophic neurologic injury until the intent to donate is known.[38] One study showed that only 15% of donors met DMGs at the time of consent, although the rate was higher immediately before organ procurement.

Management of Donors After Circulatory Death

The majority of DCD donors are patients awaiting cardiac arrest in the ICU (category III). To minimize warm ischemia time, life support is usually withdrawn in the surgical unit. However, the family's desire to be present has led some institutions to withdraw life support in other nearby locations. The procurement team should not take part in patient management before a determination of irreversible death, which includes the period during which withdrawal of support and declaration of death occur. The administration of pharmacologic drugs for the purpose of maximizing donation potential, particularly therapies capable of hastening death, is controversial. However, narcotics and benzodiazepines are commonly continued and can be titrated to blunt sympathetic responses. Premortem administration of heparin can facilitate organ procurement but, because of the bleeding risk, is omitted in some institutional policies. Most protocols require specific consent for premortem donor therapy.

Invasive premortem techniques for reducing warm ischemia time have been described. These include cannulation of the femoral artery and vein before the withdrawal of life support, which allows rapid infusion of cold preservation solution after the declaration of death. These cannulas can also be used for extracorporeal membrane oxygenation (ECMO) after death. However, the postmortem use of ECMO to restore the blood flow to vital organs generates vigorous debate, which highlights the ongoing ethical questions in donor management—the need to protect the best interest of the dying patient, while facilitating his or her wish to donate.[39]

Management of Organ Donor During Procurement Surgery

Anesthesia care for organ procurement is required only in the case of neurologic-dead donors. The majority of organ procurement occurs at community hospitals, not tertiary medical centers. As a result, the logistics of organ procurement, the social circumstances, and the unusual sequence of intraoperative events may seem intimidating to the anesthesiologist.

Surgical techniques may vary, depending on whether single or multiple organs are procured. Generally, wide exposure of the surgical field is established via a midline laparotomy extended by sternotomy. A cannula is placed in the aorta to flush the organs with the cold preservation solution. Ice is applied to the surgical field to further protect the organs. The organs are removed with their vascular structures after isolation in an order according to their susceptibility to ischemia, with the heart first and the kidney last.

Most donors arrive in the surgical unit with an endotracheal tube in place, and supported by the intravenous administration of vasoactive drugs. During procurement surgery, patients can have movements resulting from spinal reflexes; therefore, neuromuscular blockers are desirable. Spontaneous spinal reflex or surgical stimulation can cause catecholamine release and hypertension. Hypertension can be managed by a number of drugs including vasodilators, opioids, and anesthetics; however, volatile anesthetics are commonly preferred. As previously mentioned, volatile anesthetics may provide additional benefits that include ischemic preconditioning and the reduction of ischemia-reperfusion injury.[40]

The intravascular administration of fluids and vasoactive drugs can treat blood loss and cardiovascular instability caused by surgical manipulation. Maintaining hemodynamic stability allows surgeons to procure the organs without further damage to the organs. Vasodilators such as phentolamine or alprostadil (for lung recovery) may be administered during cross-clamping with the goal of decreasing systemic vascular resistance and allowing an even distribution of the preservation solution. Clinically significant bradycardia in neurologic-dead donors does not respond to atropine; therefore, a direct-acting chronotrope such as isoproterenol should be readily available. Heparin is usually administered before cross-clamping the aorta. If recovery of the heart or lung is anticipated, then pulmonary artery catheters and/or CVP catheters need to be withdrawn before cross-clamping. If lung recovery is anticipated, then the lungs are ventilated well beyond cross-clamping. Communication between the surgical team and the anesthesiologist is crucial to ensure optimal organ quality. As soon as the organs are perfused with the cold solution, mechanical ventilation and anesthesia care can be stopped.

Management of Living Organ Donors

Living donor organ transplantation has been successfully used as an alternative to deceased donor transplantation. In the United States the number of living donor organ transplants has remained flat since 2011.[3] In some Asian countries such as Japan and Korea, living donor transplantation is a standard procedure since DND is unusual because of cultural beliefs in these countries. Living donor organ transplantation has some advantages. The procedure can be scheduled as elective surgery at the same facility, which allows donor and recipient surgeries to be coordinated and the cold ischemia time to be minimized. Additionally, the graft is not exposed to the physiologic alterations associated with DND or DCD donors. Living donors direct their donation to a specific recipient; therefore, the timing of the transplant can be optimized for the recipient, and prolonged waiting times associated with deceased donor transplantation are typically avoided. As a result, the recipient is generally in better overall condition. Although living organ transplantation has its advantages, it exposes healthy donors to medical risks. Additional concerns are potential decreased quality of life and an adverse financial impact after donation. The ethical aspect of living organ donation, particularly liver donation, continues to be vigorously scrutinized.[41,42]

Living donation should be preceded by a thorough medical, psychologic, and social evaluation that confirms the absence of contraindications and the lack of coercion. The informed consent includes full disclosure of possible complications and is facilitated by a patient advocate in many institutions with no relationship to the recipient. In the past, donors were typically related to the prospective recipient. Now, living unrelated donors make up a greater proportion of living kidney transplant in the United States.[1] Paired or chain donation allows two or more recipients with incompatible living donors to exchange donors, improving the graft match for both recipients. Similar to the expansion of deceased donor criteria, living donor criteria have been extended to include donors of advanced age and those with obesity.[43] Living multi-organ donation from a single donor, either simultaneously or sequentially, although rare, has been reported. Careful selection of such donors, disclosure of risks, and close follow-up are needed.[44]

LIVING KIDNEY DONOR

Because the kidney is a paired organ, it is a natural choice for living donation. The first successful kidney transplant was a living organ transplant performed between identical twins in 1954. Now, living donors account for approximately 29% of kidney transplants in the United States.[1,45] Living donor kidney transplantation provides the optimized timing for transplant and can avoid pretransplant dialysis, which is associated with improved survival.[46] In addition, living donor grafts provide better function and last longer than grafts from deceased donors.[47] A wide range of medical and nonmedical factors need to be considered to ensure donor safety. To ensure a sufficient reserve after donation, many transplant centers use a glomerular filtration rate (GFR) greater than 80 $mL/min/1.73\ m^2$ as a cutoff for donation. GFR is typically estimated by the measurement of urine creatinine clearance. If the estimated GFR is marginal, then radioactive and nonradioactive tracers can provide additional information.[48] Some centers allow a lower GFR.[49]

Traditionally, living kidney donor surgery was performed via open nephrectomy via a subcostal lateral incision. Now, it is commonly performed via laparoscopy. With this approach, donors experience less postoperative pain, a faster recovery, and a shorter hospital stay.[49] Either the left or the right kidney can be used for transplant; however, the left kidney is usually preferred because of the easier surgical exposure and longer vascular supply. The right kidney has a short vein, and its artery courses posterior to the inferior vena cava.

The patient is placed in a lateral position with the table flexed and the kidney rest elevated. The surgical procedure begins with mobilization of the kidney with subsequent identification and dissection of the ureter, renal vein, and artery, and separation of the adrenal vein. When the right donor nephrectomy is performed, additional steps include duodenal mobilization and separation of the kidney from the liver. After mobilization of the kidney and clamping of the vascular structures, the kidney is retrieved through a small incision by either a hand-assisted or non–hand-assisted technique. Donor nephrectomy can be performed via a transabdominal route but is increasingly accomplished via a retroperitoneal approach using minimally invasive techniques. The advantage of a retroperitoneal approach is less manipulation of intraabdominal viscera. Single-incision donor nephrectomy has been described using uniquely designed devices. Recently, robotic-assisted laparoscopic living donor nephrectomy has been reported.[49,50] This technique may further decrease the trauma and discomfort to the donor.

Anesthetic management of elective laparoscopic donor surgery on a healthy patient is similar to that used for elective laparoscopic nephrectomy. Standard noninvasive monitors are usually sufficient. One or two large-bore peripheral intravenous lines are usually placed. Transfusion of red blood cells is rare; however, type and screen, or type and cross for 1 to 2 units of blood, is routine practice in some centers in case of injury to major vessels. General anesthesia is required for laparoscopic nephrectomy and general anesthesia combined with epidural anesthesia is often used if open nephrectomy is planned.

Although laparoscopic nephrectomy on a healthy patient may be routine, some concerns in addition to potential blood loss exist. High intraabdominal pressure reduces venous return and has been associated with postoperative renal dysfunction. Lower insufflation pressure may prevent compression of the renal veins and parenchyma.[51] Adequate intravascular fluid administration appears to be the best strategy to preserve kidney function. Some advocate liberal fluid administration (10-20 mL/kg/h), although laparoscopic nephrectomy is typically associated with minimal blood loss. Others use urinary output as an indicator for fluid management. To ensure that the urinary output is greater than 2 mL/kg/h, fluid is usually given in excess of the physiologic need throughout the procedure. The surgeon may request the administration of furosemide and/or mannitol during the surgery for the purpose of increasing urine output. The preferred type of fluid for intravascular volume expansion during donor nephrectomy is not known. In the absence of evidence, most centers use an isotonic crystalloid solution. Nitrous oxide is best avoided because of a concern over bowel distention and poor surgical exposure. Intravenous heparin (3000-5000 international units [IU]) is often administered immediately before the renal vessels are clamped. Protocols may vary among institutions, and close communication with the transplant surgeon is essential. If hypotension occurs after adequate fluid replacement, then dopamine and ephedrine are preferable to direct-acting vasopressors to minimize vasoconstriction in the graft. After the kidney is retrieved, anesthesiologists should be prepared for a quick closure and ensure that neuromuscular blockade is reversed.

Mild or moderate pain after laparoscopic nephrectomy originates from the port insertion, the abdominal incision, pelvic organ manipulation, diaphragmatic irritation, and/or ureteral colic. Postoperative pain can be easily managed in most patients with supplemental intravenous opioids in the early postoperative period and later with oral opioids and acetaminophen. Nonsteroidal antiinflammatory drugs should be used with caution because of their potential prostaglandin-mediated adverse renal effects. Pain after open nephrectomy with subcostal lateral incision is severe and can last several days, which can limit the patient's efforts to breathe, cough, and move, leading to atelectasis and postoperative infection. Postoperative epidural analgesia should be considered for pain relief in these patients.

Post-donation complications reported to the Organ Procurement and Transplantation Network within 6 weeks of surgery include the need for blood transfusion (0.4%), readmission (2.1%), interventional procedures (0.9%), and reoperation (0.5%).[45] A study of more than 80,000 living kidney donors showed a 90-day mortality of 3.1 per 10,000 donors (0.03%) and remains unchanged in the last 15 years.[52] Pulmonary embolism occurred in 0.1% of donors and is the main cause of mortality.[45] Kidney donors are at moderate risk for developing venous thromboembolism; therefore, intermittent pneumatic compression devices and prophylactic heparinization are recommended until ambulation. A decrease of approximately 30% in GFR can be expected after donation, and most donors will maintain a GFR greater than 60 mL/minute at 3 months.[49] Donor nephrectomy does not appear to increase long-term mortality or end-stage renal disease. Within the donor population, the likelihood of postdonation chronic kidney disease, hypertension, and diabetes is relatively higher among certain subgroups, such as African-American and obese donors, but the impact of unilateral nephrectomy on the lifetime risks of adverse events in these subgroups is unknown because the risks without nephrectomy have not been defined.[45] It should be noted that all studies on post-donation complications are retrospective without long-term follow-ups and matched controls.

LIVING LIVER DONOR

Living donor liver transplantation (LDLT) was first introduced in 1988 for pediatric recipients[53] and later expanded to adult recipients. Although LDLT is commonly performed in some Asian countries, it only consists of a small portion (<5%) of overall liver transplants performed in the United States.[3] The primary concern, that of harm to a healthy, altruistic donor, is greater in LDLT, compared with kidney donation.

The liver's remarkable reserve, coupled with its unique capacity to regenerate, forms the basis for LDLT. After resection of as much as two-thirds of the liver, the donor's liver regains its original size in 2 to 3 weeks.[54] A portion of the adult liver (typically the left lobe or left lateral segment) transplanted to a pediatric recipient will grow with the recipient. Most LDLTs are electively performed in patients with chronic liver disease. Emergent LDLT is uncommon but is occasionally performed for acute liver failure. LDLT performed in patients with very advanced disease generates considerable debate.

The determination of donor liver volume and anticipated graft size is unique to LDLT. Formulas using demographics, including body weight, height, age, and sex, have been developed. Methods using radiologic or ultrasonic measurements also have been proposed.[55] Accurate estimation of donor liver volume and intended liver graft volume is critical to avoid small-for-size syndrome in the recipient and to preserve adequate remnant liver volume in the donor.[56] For pediatric LDLTs, the left lateral segment (segments II and III) or a total left hepatic lobectomy (segments II, III, and IV) is generally enough to provide sufficient liver mass (Fig. 61.3). From a surgical point of view,

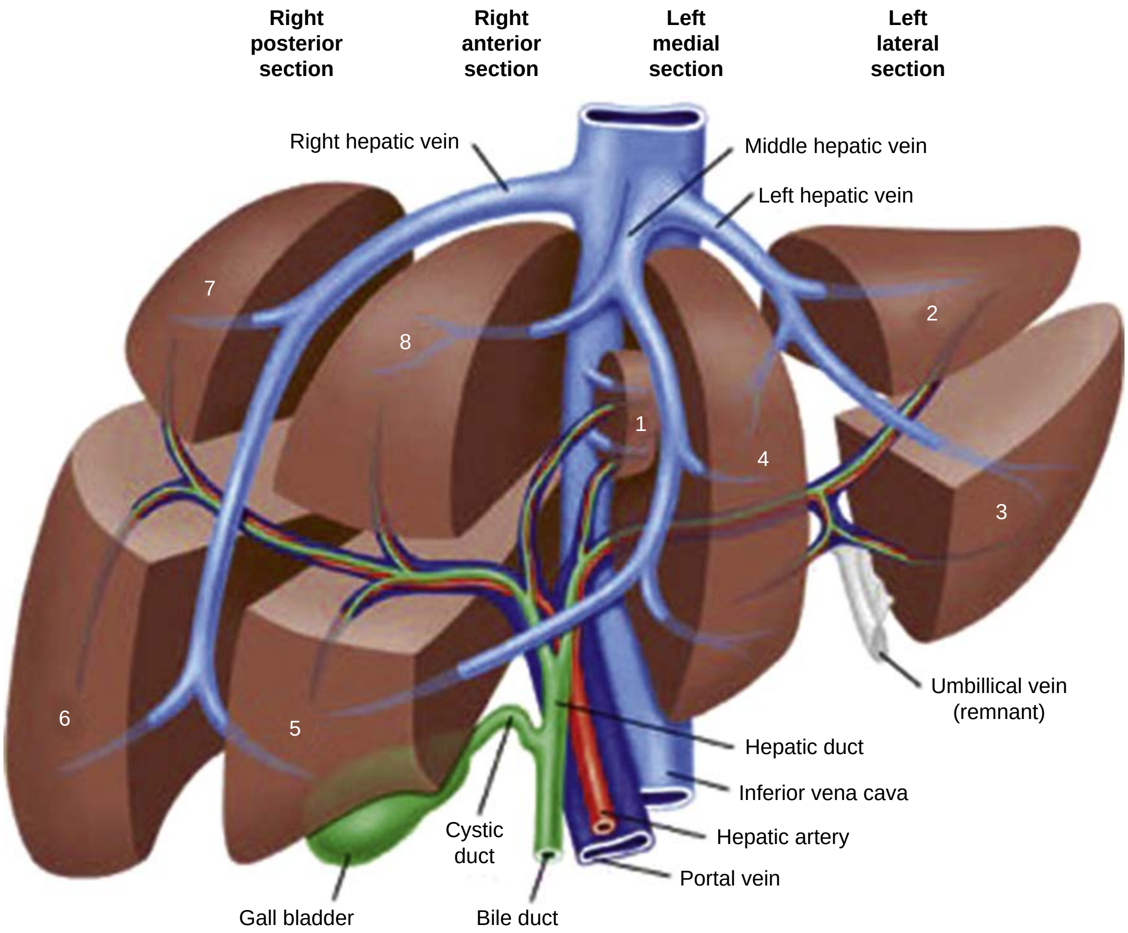

Fig. 61.3 Segmental liver anatomy illustrates the segments resected during various partial hepatectomies. (Redrawn from Steadman RH, Braunfeld M, Park H. Liver and gastrointestinal physiology. In: Hemmings HC, Egan T, eds. *Pharmacology and Physiology in Anesthesia: Foundations and Clinical Applications*. Philadelphia: Saunders; 2013:475–486.)

a left hepatectomy is less complex, and the duration of surgery is shorter. Since the first report in 2002, more living donor left lobectomies are performed using laparoscopy.[57] For adult-to-adult LDLT, right hepatic lobectomy is usually required. The surgical technique for right hepatectomy involves separation of the right hepatic lobes (segments V, VI, VII, and VIII) from the left. Compared with left hepatectomy, right hepatectomy is technically more challenging and associated with more perioperative risk. Right hepatectomy results in a graft weighing 500 to 1000 g, which leaves the donor with approximately one-third of the original liver mass. If one donor cannot provide sufficient liver mass, then a technique using two donors to one recipient has been reported.[58] For a small recipient, the left lobe of a large donor organ may suffice.

Anesthetic management starts with a preoperative discussion with the donor patient and family that addresses the risks and concerns associated with the procedure. Most transplant programs provide extensive educational materials, discussion, and support, beginning well before the day of surgery. General anesthesia with neuromuscular blockade is required for living liver donation surgery. The patient is placed in a supine position and intraoperatively uses the reverse Trendelenburg position to facilitate the exposure of the liver. Two large-bore intravenous catheters are placed. Standard noninvasive monitors and arterial blood pressure monitoring are typically used. A nasogastric tube is placed for decompression of the stomach and surgical exposure.

An L-shaped or standard bilateral subcostal incision with a midline extension is frequently used in living donor surgery. During mobilization of the liver and its vasculature, manipulation of the liver occasionally results in decreased venous return to the heart with episodes of hypotension. The return of the liver to its orthotopic position will relieve the venous obstruction; alternatively, administering short-acting vasoactive agents and/or a fluid bolus will generally treat the problem. Most blood loss occurs during transection of the liver parenchyma. With surgical devices specifically designed for hepatectomy, blood loss during living donor hepatectomy is significantly reduced. After the vasculature of the donor lobe is clamped and divided, the graft is removed, and the vasculature and bile duct are oversewn. The abdomen is closed after hemostasis is achieved.

Blood loss during hepatectomy is a major concern and is associated with adverse outcomes. Placement of the CVP catheter and the use of low CVP (<5 cm H_2O) technique are advocated in some centers to reduce blood loss and transfusion requirements.[59] Low CVP reduces blood loss by increasing venous drainage from the hepatic sinusoids and decreasing blood backflow.[59] In addition, low CVP may reduce graft edema and improve postoperative graft function.[51] Low CVP is most often achieved by intravascular fluid restriction and sometimes by drugs, including diuretics and vasodilators.[59] Others consider the placement of a CVP catheter and low CVP technique unnecessary during hepatic resection surgery because of the inability to demonstrate a relationship between CVP and blood loss.[60] Other factors, including steatosis, body weight, and sex, may be more important than CVP in influencing blood loss during living donor hepatectomy.[61] Potential drawbacks of the low CVP technique are the risk of CVP catheter placement and difficulty reversing hemodynamic disturbances in the event of massive bleeding. Others point out that the use of low CVP originates from early experience with hepatectomy several decades ago, when blood loss was significant. With improved surgical techniques and equipment, blood loss during hepatectomy has been dramatically reduced, making CVP placement and monitoring unnecessary.[60,61] At the authors' institution, CVP placement is rarely used. Peripheral venous pressure measurements in the arm may be measured as an alternative to conventional CVP measurements.[62]

Several other blood-saving strategies have been used in living donor hepatectomy. These include cell salvage techniques and preoperative donation of 1 to 2 units of autologous blood, which reduces the chance of allogeneic blood transfusion. Intraoperative isovolemic hemodilution with retrieval of 1 to 2 units of blood in the surgical unit can minimize the likelihood of blood transfusion.[63] The application of one or more of the blood-saving strategies previously listed is usually sufficient in the vast majority of patients.[60] After the graft is removed, excessive intravascular volume should be avoided because it may impede venous return and result in congestion of the remnant liver.[51]

Most living liver donors can be extubated at the end of the procedure in the surgical unit and transferred to the postoperative care unit. Discontinuation of mechanical ventilation reduces intrathoracic pressure, which reduces congestion in the remnant liver. Admission to the ICU is generally unnecessary but preferred in some institutions. Caution is required with the use of intravenous analgesics and opioids in the immediate postoperative period. The remnant liver is assumed to have some degree of insufficiency, although this assumption has not been thoroughly investigated.[51] Optimal perfusion of the remnant liver is achieved by the maintenance of adequate cardiac output and an avoidance of hypovolemia, anemia, and hypothermia-induced coagulopathy.[51]

The use of epidural anesthesia for postoperative pain control in living donor surgery remains controversial. Similar to other upper abdominal surgery, postoperative epidural analgesia provides excellent pain control with less sedation, compared with intravenous patient-controlled analgesia.[64] By facilitating pulmonary toilet, epidural analgesia reduces the risk of respiratory infections. Despite these advantages, preoperative placement of a thoracic epidural catheter is routinely performed in some transplant centers and is entirely avoided in others. The difference of practice originates from the development of postoperative coagulopathy in patients after donor hepatectomy. Postoperatively, thrombocytopenia occurs while the prothrombin and activated partial thrombin times are prolonged. These changes peak on postoperative day 2 to 3, followed by a steady trend toward normalization in the following days.[65] Thus, concern over the potential development of an epidural hematoma is the basis for avoiding epidural catheter placement. Several studies examining the use of the epidural catheter in this population report no adverse effects. In a study of 755 donors who received an epidural catheter for postoperative pain management, no complications associated with the epidural catheter were reported.[66] Another study including 242 living liver donors also showed that epidural analgesia seems to be a safe option when carefully used.[65] Another piece of evidence supporting epidural placement is that hypercoagulability, not hypocoagulability measured by thromboelastography, can develop in the majority of patients after hepatectomy.[67,68] Despite the low overall incidence of epidural hematoma, these studies are criticized for a lack of power to assess the risk of this rare event. If the epidural catheter is placed, then the catheter should not be removed until satisfactory coagulation parameters have been retained, which usually takes 3 to 5 days.[51] If the epidural catheter is not placed, then patient-controlled analgesia is used. The choice of pain-control strategy is influenced by the patient's expectations, surgical preferences, institutional consensus, postoperative monitoring capabilities, and nursing staff familiarity with the various techniques.

Worldwide, a number of LDLT-related donor complications, including mortality, have been reported.[69,70] A multicenter observational study of 760 adult-to-adult LDLTs with up to 12 years of follow-up revealed that 40% of donors had complications (Table 61.4).[69] A total of 19% of donors had more than one complication. Although most of the complications were not associated with residual disability, some were severe. Infection is the most common complication and biliary complications such as bile leaks or stricture can be difficult to treat and can lead to prolonged hospital stays with the possibility of further surgery. Higher preoperative creatinine levels, intraoperative hypotension, and intraoperative transfusion are associated with donor complications. Increased institutional experience is not associated with decreased complications.[69] Another recent study involving 5202 living donor hepatectomies found that 12% of donors developed at least one complication, of which 3.8% were major events, which doubled after right hepatectomy.[71]

LIVING LUNG DONOR

Living lung transplantation is an alternative to deceased lung transplantation. Typically, two donors are used for one recipient in living lung transplantation, although the use of a single living donor has been reported.[72] If two donors are involved, then careful coordination and timing of the anesthetic induction of the two donors and recipient are required. The right lower lobe of one donor and the left lower lobe of the second donor are implanted in the recipient in place of the whole right and left lungs. Donor lobectomy requires sufficient bronchial, arterial, and vein cuffs to permit successful anastomoses. A bronchial air leak can result in a prolonged need for chest tube drainage, which lengthens hospital stay.

After the induction of general anesthesia, a single-lumen endotracheal tube is usually placed initially to facilitate fiberoptic bronchoscopic examination before incision. Once

TABLE 61.4 Type and Frequency of Complications of Living Liver Donors of 760 Donor Procedures, ~40% (296 Donors) Suffered 557 Complications; 20 Procedures Were Aborted)

Complications	Frequency (% of 760 procedures)
Infections	13.2
Pleural effusion	11.0
Bile leak or biloma	8.1
Incisional hernia	6.6
Psychologic difficulty	5.6
Neuropraxia	3.4
Ascites	2.8
Unplanned reexploration	2.7
Pulmonary edema	2.1
Bowel obstruction	1.6
Intraabdominal abscesses	1.2
Pulmonary embolism	1.0
Pneumothorax	0.8
Deep vein thrombosis	0.8
Biliary stricture	0.7
Portal vein thrombosis	0.5
Inferior vena cava thrombosis	0.4

Modified from Abecassis MM, Fisher RA, Olthoff KM, et al. Complications of living donor hepatic lobectomy—a comprehensive report. *Am J Transplant*. 2012;12:1208–1217.

a decision is made to proceed, a left-sided double-lumen endotracheal tube later replaces the single-lumen endotracheal tube. Standard noninvasive monitors, intraarterial blood pressure monitoring, and capnography may be sufficient. After placing the donor in the lateral decubitus position and rechecking the double-lumen tube position by fiberoptic bronchoscope, a thoracotomy is performed. Intraoperative cardiorespiratory and metabolic homeostasis minimizes the risk of postoperative complications. Prostaglandin E_1 is usually intravenously administered to dilate the pulmonary vessels with titration according to systemic blood pressure (hypotension needs to be avoided). After mobilization is complete, the lung is reinflated for 5 to 10 minutes, followed by the administration of heparin and a steroid. Transection of the lung is performed after the lung is recollapsed.

Thoracic epidural analgesia is a useful adjunct for perioperative care. The epidural catheter may be placed hours before surgery.[51] Although this approach may be questionable in patients undergoing heparinization, the superiority of postoperative analgesia and the avoidance of atelectasis and infection appear to justify the risk of donor epidural catheterization.[73]

ISCHEMIA-REPERFUSION INJURY

Ischemia-reperfusion injury of transplanted grafts is unavoidable if blood supply is interrupted. An interruption of the blood supply during the ischemic period results in metabolic and pathophysiologic changes. Restoration of blood flow and reoxygenation can also cause tissue injury, as well as profound immune and inflammatory responses.[74]

Ischemia-reperfusion injury results from a wide range of pathologic processes. During ischemia, a lack of oxygen supply leads to a depletion of adenosine triphosphate (ATP) and glycogen. Without ATP, sodium-potassium (Na-K) pumps cannot maintain ion gradients across the cellular membrane. As a result, extracellular sodium ions move into cells, causing swelling. Vascular permeability is increased since intracellular cyclic adenosine monophosphate levels and adenylate cyclase activity is decreased.[74,75] The restoration of the blood supply causes a series of pathophysiologic changes that lead to tissue injury. Reperfusion-related injuries include necrosis, apoptosis (programmed death), and autophagy-associated cell death. Reperfusion also activates autoimmune responses including natural antibody recognition of neoantigens, activation of the complement system, activation of innate and adaptive immune responses, and cell migration to the affected area.

Organ Preservation and Management After Procurement

After procurement, preservation of organs in a cold (4°C) solution until reperfusion remains a mainstream management after procurement. Although static cold preservation slows the metabolic rate, energy consumption is not completely stopped. Accumulation of metabolites and intracellular calcium limit the maximum time for static cold storage.[76] Various cold-storage solutions are used worldwide with the UW solution one of the most widely used. The UW solution contains high potassium and adenosine to supply ATP during cold storage. Histidine-tryptophan-ketoglutarate (HTK) solution, originally developed for cardioplegia and subsequently applied to organ preservation in Europe, has gained popularity.[77] The potential for hyperkalemia during organ reperfusion (particularly with the liver) increases when the UW solution is used, compared with the HTK solution. However, the graft is typically flushed with colloid before reperfusion, regardless of the solution used, which decreases the likelihood of severe hyperkalemia. Recent data suggest that the HTK solution may be associated with poor graft function in abdominal organ transplantation.[78,79] Organ-specific solutions, such as Perfadex solution (manufactured by Vitrolife in Göteborg, Sweden) for the lung and Celsior solution (manufactured by Genzyme in Cambridge, MA) for the heart, are available. Although ischemia time should be kept minimal, a longer storage time allows transportation of the graft to the highest acuity patient for a long distance. Generally accepted cold ischemia times during static cold preservation are 24 hours for the kidney, 12 hours for the liver, 6 hours for the heart, and 4 hours for the lung.

In addition to static cold preservation, machine perfusion can be used to preserve procured organs. The driving force for recent renewed interest in machine perfusion is to expand the donor pool.[79] The potential advantage for machine perfusion techniques include a longer storage time, ability to assess the viability of organ, and potential therapeutic interventions during preservation. Temperature during

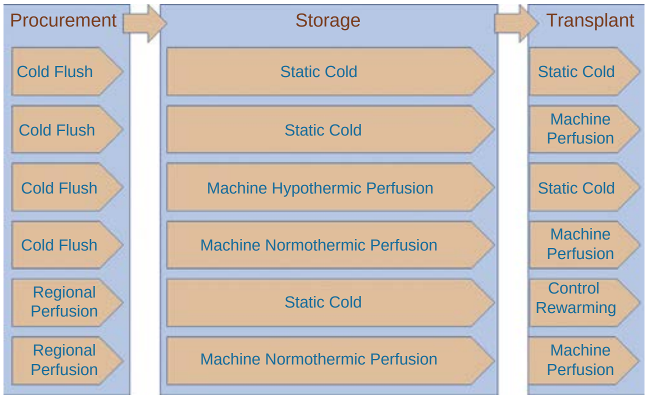

Fig. 61.4 Various techniques and combination of techniques can be used to improve donor function and recipient outcome during procurement, preservation, and transplant.

machine perfusion can be hypothermic (4°C-10°C), subnormothermic (12°C-30°C), and normothermic (35°C-37°C). Different temperatures have different advantages and disadvantages.[76] When normothermia is used, oxygen needs to be added. Combination of different techniques and temperatures may be used in different situations (Fig. 61.4).[79] Clinical trials and metaanalysis suggest machine perfusion improves short-term outcomes including a reduction in DGF and primary nonfunction. These effects are more obvious in high-risk donors.[76,80-82] Changes of biomarkers in perfusate reflect damage of preserved organs and may be used to predict posttransplant outcome. Tests using metabolomics, proteomics, and genomics approaches may provide useful information in the future.[83] Several pharmacologic and biologic agents have been tested in animal models and preclinical trials; some, including recombinant agents that block leukocyte adhesion, have shown promise.[84,85] Preconditioning with volatile anesthetics has been shown to protect tissue from ischemia-reperfusion injury in animal models.[86] In human trials, volatile anesthetics have some beneficial effects in the setting of myocardial infarction, minimizing ischemia-reperfusion injury, although the data remain inconclusive.[87]

Anesthesia for Obstetrics

EMILY E. SHARPE and KATHERINE W. ARENDT

KEY POINTS

- The normal physiologic changes of pregnancy begin in the first trimester, affect all organ systems, and alter pharmacokinetic and pharmacodynamic responses to many drugs commonly used in anesthesia.
- Maternal-fetal exchange of most drugs and other substances occurs primarily by diffusion. The rate of diffusion and peak levels in the fetus depend on maternal-to-fetal concentration gradients, maternal protein binding, molecular weight of the substance, lipid solubility, and the degree of ionization of that substance.
- All women in labor are considered to have a full stomach and an increased risk for pulmonary aspiration of gastric contents during induction of anesthesia and aspiration prophylaxis should be considered before all surgical procedures during pregnancy.
- Uterine blood flow increases progressively during pregnancy from approximately 100 mL/min in the nonpregnant state to between 700 and 900 mL/min (~10% of cardiac output) at term gestation. Consequently, hemorrhage during pregnancy carries significant morbidity and is a leading cause of maternal death worldwide. Early recognition with timely intervention, optimal team performance, and appropriate blood product transfusions are essential to patient outcomes.
- Uterine and placental blood flow depend on maternal cardiac output and are directly related to uterine perfusion pressure and inversely related to uterine vascular resistance. Decreased perfusion pressure can result from maternal hypotension secondary to hypovolemia, aortocaval compression, sympathetic blockade, and decreased systemic resistance from either general or neuraxial anesthesia. Prophylactic or therapeutic phenylephrine in boluses or as an infusion reduces the incidence and severity of hypotension from spinal anesthesia for cesarean delivery. In comparison to ephedrine, phenylephrine results in less fetal acidosis.
- During pregnancy, the maternal oxyhemoglobin dissociation curve shifts to the right with pregnancy while the fetal oxyhemoglobin dissociation curve lies to the left. This facilitates oxygen transfer from maternal to fetal hemoglobin. Fetal O_2 saturation does not exceed 60% even with 100% O_2 delivery to the mother. Maternal $PaCO_2$ decreases from 40 mm Hg to approximately 30 mm Hg during the first trimester. This reduction facilitates carbon dioxide transfer across the placenta, which is primarily limited by blood flow and not diffusion.
- Labor is a continuous process separated into first, second, and third stages. The first stage of labor includes the change of the uterine cervix from a thick closed tube to an opening of approximately 10 cm through which the fetus can be expelled. This stage is further divided into latent and active phases.
- Neuraxial analgesia is the most reliable and effective method of reducing pain during labor. Adequate analgesia is achieved with blockade of T10 to L1 during the first stage of labor and requires extension to include S2 to S4 during the second stage of labor.
- Neuraxial analgesia in comparison to unmedicated birth or intravenous opioid analgesia may prolong the second stage of labor but does not increase the risk for cesarean delivery. Epidural analgesia inserted *early* compared to *late* in labor does not increase the risk for cesarean delivery or prolong the first stage of labor.
- Remifentanil patient-controlled analgesia (PCA) may offer superior pain relief and less fetal effects than other intravenous opioid analgesics but its analgesic effects are inferior to epidural labor analgesia and it requires careful maternal oxygenation and ventilation monitoring.
- Hypertensive disorders of pregnancy complicate 5% to 10% of worldwide pregnancies and can cause maternal and fetal mortality. Patients with preeclampsia are at increased risk for cerebral hemorrhage, pulmonary edema, and coagulopathy. Systolic and diastolic blood pressure higher than 160/110 mm Hg should be treated to prevent intracerebral hemorrhage.
- Sepsis is a leading cause of maternal morbidity and mortality in the UK and United States. Early identification and treatment has been shown to improve outcomes.

Physiologic Changes During Pregnancy and Delivery

During pregnancy and the peripartum period, substantial changes in maternal anatomy and physiology occur secondary to (1) changes in hormone activity, (2) mechanical effects of an enlarging uterus, and (3) increased maternal metabolic demands and biochemical alterations induced by the fetoplacental unit. These changes have a significant impact on anesthetic pharmacology and physiology resulting in unique anesthesia management requirements during pregnancy. Pregnant women with comorbid conditions require even greater anesthetic modifications.

CARDIOVASCULAR CHANGES

Changes in the cardiovascular system occur throughout gestation and include (1) anatomic changes, (2) an increase in intravascular volumes, (3) an increase in cardiac output, (4) a decrease in vascular resistance, and (5) the presence of supine hypotension. Table 62.1 and the following sections detail these changes.

Physical Examination and Cardiac Studies

The cardiovascular changes of a normal pregnancy are significant. In cardiac auscultation an accentuated first heart sound (S_1) can be heard, with an increased splitting noted from dissociated closure of the tricuspid and mitral valves. A third heart sound (S_3) is often heard in the final trimester, and a fourth heart sound (S_4) can also be heard in some pregnant patients as a result of increased volume and turbulent flow. Neither the S_3 nor S_4 heart sounds have clinical significance. In addition, a benign grade 2/6 systolic ejection murmur is typically heard over the left sternal border and is secondary to mild regurgitation at the tricuspid valve from the annular dilation associated with the increased cardiac volume. Table 62.1 details the effects of pregnancy on the electrocardiogram and echocardiography. The elevation of the diaphragm by the growing uterus shifts the heart anteriorly and to the left. Left axis deviation as well as left ventricular hypertrophy are common findings in normal pregnancy. Women who present with chest pain, syncope, high-grade flow murmurs, arrhythmias, or heart failure symptoms such as hypoxia or clinically significant shortness of breath should undergo appropriate diagnostic investigation and referral.

Intravascular Volume

Maternal intravascular fluid volume begins to increase in the first trimester secondary to changes in the renin-angiotensin-aldosterone system promoting sodium absorption and water retention. These changes are likely induced by rising progesterone from the gestational sac. Plasma protein concentrations accordingly decrease with a 25% decrease in albumin and 10% decrease in total protein at term compared with nonpregnant levels.[1] Consequently, colloid osmotic pressure decreases from 27 to 22 mm Hg over the time of gestation.[2] At term, the plasma volume is 50% to 55% above the nonpregnant level. It is thought that the increase in blood volume prepares the parturient for delivery blood loss. Blood volume returns to prepregnancy values approximately 6 to 9 weeks postpartum.

TABLE 62.1 Changes in the Cardiovascular System During Pregnancy

Cardiovascular Parameter	Value at Term Compared With Nonpregnant Value
Intravascular fluid volume	Increased 35%-45%
Plasma volume	Increased 45%-55%
Erythrocyte volume	Increased 20%-30%
Cardiac output	Increased 40%-50%
Stroke volume	Increased 25%-30%
Heart rate	Increased 15%-25%
Vascular Pressures and Resistances	
Systemic vascular resistance	Decreased 20%
Pulmonary vascular resistance	Decreased 35%
Central venous pressure	No change
Pulmonary capillary wedge pressure	No change
Femoral venous pressure	Increased 15%
Clinical Studies	
Electrocardiography	Heart rate dependent decrease in PR and QT intervals Small QRS axis shift to right (first TM) or left (third TM) ST depression (1 mm) in left precordial and limb leads Isoelectric T-waves in left precordial and limb leads Small Q-wave and inverted T-wave in lead III
Echocardiography	Heart is displaced anteriorly and leftward Right-sided chambers increase in size by 20% Left-sided chambers increase in size by 10%-12% Left ventricular eccentric hypertrophy Ejection fraction increases Mitral, tricuspid, and pulmonic valve annuli increase Aortic annulus not dilated Tricuspid and pulmonic valve regurgitation common Occasional mitral regurgitation (27%) Small insignificant pericardial effusions may be present

TM, Trimester.

Cardiac Output

By the end of the first trimester, maternal cardiac output typically increases approximately 35% to 40% above prepregnancy values and continues to increase 40% to 50% by the end of the second trimester.[3-5] Cardiac output remains stable throughout the third trimester. This increased cardiac output is secondary to increases in both stroke volume (25%-30%) and heart rate (15%-25%).[6,7] Labor further increases cardiac output, which fluctuates with each uterine contraction. Increases above prelabor values of 10% to 25% occur during the first stage and 40% in the second stage. The largest increase in cardiac output occurs immediately after delivery, when cardiac output can increase by 80% to 100% more than prelabor values.[8] This abrupt increase is secondary to the autotransfusion of uteroplacental blood as the evacuated uterus contracts, reduced maternal vascular capacitance from loss of the intervillous space, and diminished lower extremity venous pressure from release of the aortocaval compression. This large fluctuation in cardiac output presents a unique postpartum risk for patients with cardiac disease, especially those whose heart cannot accommodate an increase in cardiac output such as those with fixed valvular stenosis or pulmonary vascular hypertension. Cardiac output returns toward prelabor values within 24 hours postpartum depending on the mode of delivery and degree of blood loss.[9] Cardiac output decreases substantially toward prepregnant values by 2 weeks postpartum, with complete return to nonpregnant levels between 12 and 24 weeks after delivery.[10]

Systemic Vascular Resistance

Although cardiac output and plasma volume increase, systemic blood pressure decreases in an uncomplicated pregnancy secondary to a reduction in systemic vascular resistance. Systemic vascular resistance decreases as a result of the vasodilatory effects of progesterone and prostaglandins as well as the low resistance of the uteroplacental vascular bed.[11] Although affected by positioning and parity, systolic, diastolic, and mean blood pressure may all decrease 5% to 20% by 20 weeks gestational age and then gradually increase toward nonpregnant values by term.[12-14] Diastolic arterial blood pressure decreases more than systolic arterial blood pressure resulting in a slight increase in pulse pressure. Central venous and pulmonary capillary wedge pressures do not change during pregnancy,[6] despite the increased plasma volume, because venous capacitance increases.

Aortocaval Compression

Aortocaval compression by the gravid uterus as a result of supine positioning is associated with a decrease in systemic blood pressure. Although the inferior vena cava is compressed in nearly all term parturients,[15] supine hypotension syndrome (also known as aortocaval compression syndrome) is experienced by only 8% to 10% of women.[16] Supine hypotension syndrome is defined as a decrease in mean arterial pressure of more than 15 mm Hg with an increase in heart rate of more than 20 beats/min and is often associated with diaphoresis, nausea, vomiting, and changes in mentation. At term, the inferior vena cava can be almost completely occluded in the supine position with the return of blood from the lower extremities through the epidural, azygos, and vertebral veins that become engorged (Fig. 62.1*A*). Also, significant aortoiliac artery compression occurs in 15% to 20% of pregnant women. Inferior vena caval compression in the supine position causes a decrease in both stroke volume and cardiac output of 10% to 20% in comparison to the upright position (see Fig. 62.1*B*), and may exacerbate venous stasis in the legs and thereby result in ankle edema, varices, and increased risk for lower extremity deep venous thrombosis.

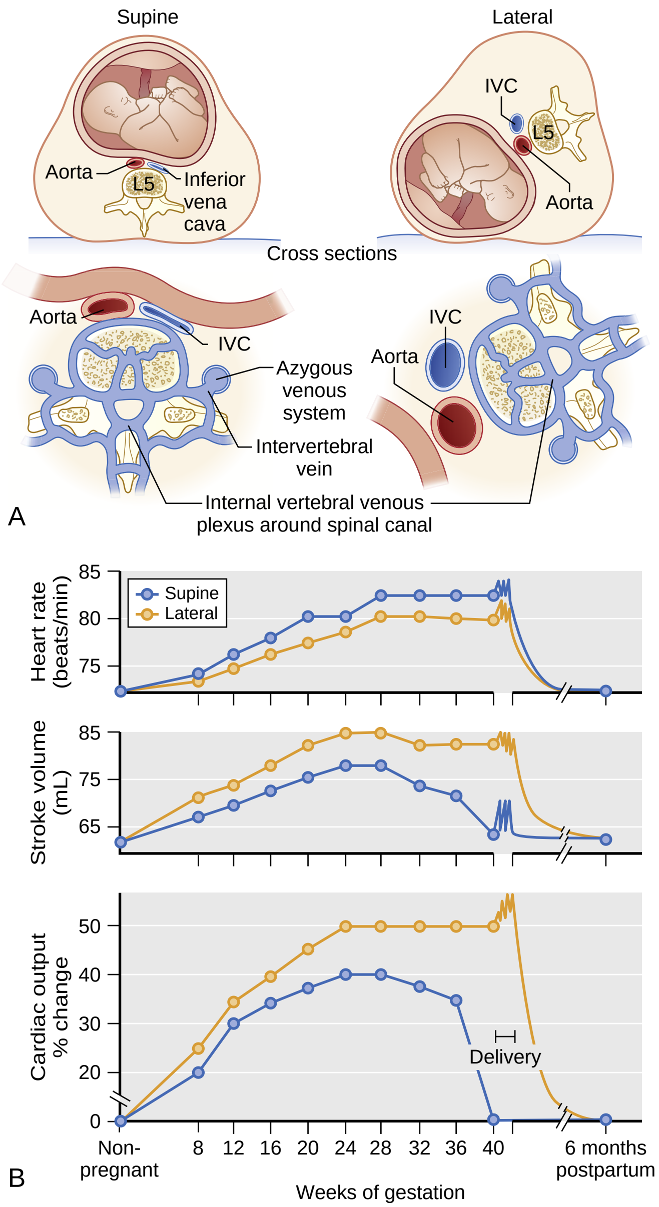

Fig. 62.1 Aortocaval compression. (A) Cross-sectional views of aortocaval compression from the gravid uterus in the supine position with loss of compression in the lateral position. (B) Alterations in heart rate, stroke volume, and cardiac output for both supine and lateral positioning with increasing gestation of pregnancy. *IVC,* Inferior vena cava. (Reprinted with permission from Bonica JJ, ed. *Obstetric Analgesia and Anesthesia*. Amsterdam: World Federation of Societies of Anaesthesiologists; 1980.)

Most pregnant women have compensatory adaptations that reduce supine hypotension symptoms despite aortocaval compression. One compensatory response is a reflexive increase in peripheral sympathetic nervous system activity. This increase in sympathetic activity results in increased systemic vascular resistance and permits arterial blood pressure to be maintained despite the reduced cardiac output. Consequently, the reduced sympathetic tone from neuraxial or general anesthetic techniques impairs the compensatory increase in vascular resistance and exacerbates the impact of hypotension from supine positioning.

Therefore in general, supine positioning is avoided during use of neuraxial techniques for labor analgesia and cesarean deliveries. Reducing the compression of the inferior vena cava and abdominal aorta with left tilt may mitigate the degree of hypotension and help maintain uterine and fetal blood flow. This is accomplished by positioning the patient laterally or by elevating the right hip 10 to 15 cm (with a historical goal of 15 degree left-tilt) with a blanket, wedge, or table tilt.

The practice of left uterine displacement has been challenged recently. In a magnetic resonance imaging (MRI) study of healthy pregnant volunteers, the volume of the inferior vena cava did not differ significantly between the supine position and the 15 degree left-tilt position but when the patients were tilted to the 30 degree left-tilt position, the inferior vena cava volume did increase.[15] Additionally, healthy women undergoing elective cesarean delivery under spinal anesthesia and a phenylephrine infusion were randomized to supine or 15 degree left-tilt position and no difference was found on neonatal acid-base status; however, the supine patients had lower cardiac output and required more phenylephrine.[17] Further studies are needed to investigate who benefits from left uterine displacement and the amount required to achieve the greatest benefit without hindering the surgical procedure. In the meantime, left uterine displacement should continue to be utilized during induction of neuraxial analgesia/anesthesia and during episodes of maternal hypotension or fetal compromise.

RESPIRATORY SYSTEM CHANGES

Pregnancy results in significant alterations in (1) the upper airway, (2) lung volumes and ventilation, and (3) O_2 consumption and metabolic rate (Table 62.2).

TABLE 62.2 Changes in the Respiratory System at Term

Pulmonary Parameter	Value Near Term Compared With Nonpregnant Value
Minute ventilation	Increased 45%-50%
Respiratory rate Tidal volume	Increased 0%-15% Increased 40%-45%
LUNG VOLUMES	
Inspiratory reserve volume	Increased 0%-5%
Tidal volume	Increased 40%-45%
Expiratory reserve volume	Decreased 20%-25%
Residual volume	Decreased 15%-20%
LUNG CAPACITIES	
Vital capacity	No change
Inspiratory capacity	Increased 5%-15%
Functional residual capacity	Decreased 20%
Total lung capacity	Decreased 0%-5%
OXYGEN CONSUMPTION	
Term	Increased 20%-35%
Labor (first stage)	Increased 40% above prelabor value
Labor (second stage)	Increased 75% above prelabor value
RESPIRATORY MEASURES	
FEV_1	No change
FEV_1/FVC	No change
Closing capacity	No change

Data from Conklin KA. Maternal physiologic adaptations during gestation, labor, and puerperium. *Semin Anesth*. 1991;10:221–234.

The Upper Airway

Capillary engorgement with increased tissue friability and edema of the mucosal lining of the oropharynx, larynx, and trachea begins early in the first trimester. As a result, an increased risk for bleeding exists during manipulation of the upper airway, in addition to an increased risk of difficult mask ventilation and intubation of the trachea. Suctioning of the airway and placement of devices should be performed gently to prevent bleeding and nasal instrumentation should be avoided. Furthermore, there is increased risk for airway obstruction during mask ventilation and both laryngoscopy and tracheal intubation are more difficult. Also, after extubation, the airway may be compromised as a result of edema, with subsequent risk for airway obstruction in the immediate recovery period.

Consequently, attempts at laryngoscopy should be minimized and experts recommend a cuffed endotracheal tube with a smaller diameter (6.0-7.0 mm internal diameter)[18,19] should be placed to minimize the chances of difficult placement secondary to airway edema. Airway edema can be more severe in patients with coexisting preeclampsia, in upper respiratory tract infections, and after active pushing as a result of associated increased venous pressure.[20] In addition, pregnancy-associated weight gain and increase in breast tissue, particularly in women of short stature or with coexisting obesity, can make insertion of a laryngoscope difficult. A patient's position should always be optimized and back-up airway instrumentation available before attempts are made at intubation of the trachea. The Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed intubation in obstetrics recommends a videolaryngoscope should be immediately available for all obstetric general anesthetics.[21]

Ventilation and Oxygenation

The increased O_2 demand and carbon dioxide production of the growing placenta and fetus cause minute ventilation to be elevated 45% to 50% more than nonpregnant values in the first trimester and for the remainder of the pregnancy. This larger minute ventilation is attained primarily as a result of a larger tidal volume and a slight increase in respiratory frequency. Maternal $PaCO_2$ decreases from 40 mm Hg to approximately 30 mm Hg during the first trimester as a reflection of the increased minute ventilation. Arterial pH, however, remains only mildly alkalotic (typically 7.42-7.44) because of metabolic compensation with increased renal excretion of bicarbonate ions (HCO_3^- is typically 20 or 21 mEq/L at term). Early in gestation, maternal room air PaO_2 is more than 100 mm Hg because of the presence

TABLE 62.3 Arterial Blood Gas Measurements in Pregnancy

Blood Gas Values	Pregnant	Nonpregnant
PaCO2	30	40
PaO2	103	100
HCO3	20	24
pH	7.44	7.4
P50	30	27

of hyperventilation and the associated decrease in alveolar CO_2. Later, PaO_2 becomes normal or even slightly decreased in the supine position, most likely reflecting small airway closure with normal tidal volume ventilation and intrapulmonary shunt. Arterial oxygenation can be significantly improved by moving the patient from the supine to the lateral position. With pregnancy, the maternal oxyhemoglobin dissociation curve shifts to the right, with the P50 (partial pressure of O_2 at which hemoglobin is 50% saturated with oxygen) increasing from 27 to approximately 30 mm Hg at term.[22] The higher P50 in the mother and lower P50 in the fetus means that the fetal blood has higher affinity for O_2 and offloading of O_2 across the placenta is facilitated. A comparison of arterial blood gas measurements in pregnant versus nonpregnant patients is summarized in Table 62.3.

At term, O_2 consumption is increased by 20% to 35%. During the first stage of labor, O_2 consumption increases above prelabor values by 40% and during the second stage it is increased by 75%. The pain of labor can result in severe hyperventilation causing $PaCO_2$ to occasionally decrease below 20 mm Hg.

Lung Volumes

During pregnancy, tidal volume increases 20% during the first trimester and increases up to 45% above nonpregnant values at term. The expanding uterus forces the diaphragm cephalad and creates a 20% decrease in functional residual capacity (FRC) by term (see Table 62.2).[23] This reduction is comprised of nearly equal reductions in both the expiratory reserve volume (ERV) and residual volume (RV). However, closing capacity (CC) remains unchanged and creates a reduced FRC/CC ratio. This results in more rapid small airway closure with reduced lung volumes, and in the supine position FRC can be less than CC for many small airways, giving rise to atelectasis. Vital capacity does not change with pregnancy. The combination of increased minute ventilation and decreased FRC results in a more rapid rate at which changes in the alveolar concentration of inhaled anesthetics can be achieved. Spirometric measurements of bronchial flow are unchanged in pregnancy.

During induction of general anesthesia, desaturation and subsequent hypoxemia occur more rapidly than in a nonpregnant patient because of decreased O_2 reserve (secondary to decreased FRC) combined with increased O_2 uptake (resulting from increased metabolic rate). Preoxygenation before general anesthesia is critical for patient safety to mitigate these physiologic changes and increase apnea time. Preoxygenation with inhalation of 100% O_2 with a goal of end-tidal oxygen fraction greater than 0.9 is recommended (can usually be obtained with 2-3 minutes of preoxygenation before induction of anesthesia) (see Chapter 44). Although the use of high-flow humidified nasal oxygen has been shown to be as effective as conventional preoxygenation in nonpregnant patients, it has not been shown to achieve acceptable preoxygenation levels in term pregnant women.[24] The increased airway edema makes both ventilation and tracheal intubation more difficult and further increases the potential for complications and morbidity of general anesthesia in pregnancy.

GASTROINTESTINAL CHANGES

After midgestation, the induction of general anesthesia places pregnant women at increased risk for regurgitation, aspiration of gastric contents, and development of acid pneumonitis. The stomach and pylorus are moved cephalad by the gravid uterus, which repositions the intraabdominal portion of the esophagus intrathoracically and decreases the competence of the lower esophageal sphincter muscle. Higher progesterone and estrogen levels of pregnancy further reduce lower esophageal sphincter tone. Gastrin, secreted by the placenta, increases gastric hydrogen ion secretion and lowers the gastric pH in pregnant women. These changes in combination with the increased gastric pressure from the enlarged uterus increase the risk for acid reflux in pregnancy. Maternal gastric reflux with subsequent esophagitis (heartburn) is common in pregnant women and increases with increased gestational age.[25] Gastric emptying is not prolonged in pregnancy.[26] Conversely, gastric emptying is decreased with the onset of labor, pain, anxiety, or administration of opioids. Increased gastric contents can further increase the risk for aspiration. Epidural analgesia using local anesthetics alone does not further delay gastric emptying; however, epidural boluses of fentanyl can cause gastric emptying delay.[27]

All women in labor are considered to have a full stomach and an increased risk for pulmonary aspiration of gastric contents during induction of anesthesia. To reduce this risk, a nonparticulate antacid, a rapid sequence induction of anesthesia technique including cricoid pressure, and endotracheal intubation are considered routine parts of general anesthesia in a pregnant woman past midgestation.

HEPATIC AND BILIARY CHANGES

Blood flow to the liver does not change significantly with pregnancy. The markers of liver function, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin, increase to the upper limits of normal with pregnancy. Alkaline phosphatase levels more than double secondary to placental production. Plasma protein concentrations are reduced during pregnancy, and the decreased serum albumin levels can result in elevated free blood levels of highly protein-bound drugs. Plasma cholinesterase (pseudocholinesterase) activity is decreased approximately 25% to 30% from the 10th week of gestation up to 6 weeks postpartum.[28-30] Although neuromuscular transmission should be analyzed before extubation, the clinical consequence of the reduced cholinesterase activity is unlikely to be associated with marked prolongation of the neuromuscular block resulting from succinylcholine.

The risk for gallbladder disease is increased during pregnancy with incomplete gallbladder emptying and changes in bile composition. Acute cholecystitis is the second most common cause of acute abdomen in pregnancy and occurs between 1 in 1600 to 1 in 10,000 pregnancies.[31]

RENAL CHANGES

Renal blood flow and the glomerular filtration rate (GFR) increase during pregnancy. Renal blood flow rises 60% to 80% by midpregnancy and in the third trimester is 50% greater than nonpregnant values. GFR is increased 50% above baseline by the third month of pregnancy and remains elevated until 3 months postpartum.[32] Therefore the clearance of creatinine, urea, and uric acid are increased in pregnancy, and the upper laboratory limits for blood urea nitrogen and serum creatinine concentrations are decreased approximately 50% in pregnant women. Levels of urine protein and glucose are commonly increased as a result of decreased renal tubular resorption capacity. The upper limits of normal in pregnancy in a 24-hour urine collection are 300 mg protein.

HEMATOLOGIC CHANGES

As previously discussed, blood volume increases during pregnancy. At term, the plasma volume has increased approximately 50% above prepregnancy values and the red cell volume has increased only approximately 25%. The greater increase in plasma volume creates a physiologic anemia of pregnancy with a hemoglobin value normally around 11.6 g/dL. Hemoglobin values less than this at any time during pregnancy are concerning for anemia. Overall oxygen delivery is not reduced by the normal physiologic anemia of pregnancy because of the subsequent increase in cardiac output. The additional intravascular fluid volume of approximately 1000 to 1500 mL at term helps compensate for the estimated blood loss of 300 to 500 mL typically associated with vaginal delivery and the estimated blood loss of 800 to 1000 mL that accompanies a standard cesarean delivery. After delivery, contraction of the evacuated uterus creates an autotransfusion of blood often in excess of 500 mL that offsets the blood loss from delivery.

Leukocytosis is common in pregnancy and is unrelated to infection. Leukocytosis is defined as a white blood cell (WBC) count greater than 10,000 WBCs/mm^3 of blood. In pregnancy, the normal range can extend to 13,000 WBCs/mm^3. WBC count may rise in labor with the degree of increase related to the duration of elapsed labor.[33] The WBC count may decrease over the first week postpartum but may take weeks or months to return to nonpregnant values.[34]

Coagulation

Pregnancy is characterized by a hypercoagulable state with a marked increase in factor I (fibrinogen) and factor VII and lesser increases in other coagulation factors (Table 62.4). Factors XI and XIII are decreased, and factors II and V typically remain unchanged. Antithrombin III and protein S are decreased during pregnancy and protein C levels remain unchanged.[35] These changes result in an approximately 20% decrease in prothrombin time (PT) and partial thromboplastin time (PTT) in normal pregnancy. Platelet count may remain normal or slightly decreased (10%) at term as a result of dilution. However, 8% of otherwise healthy women have a platelet count less than 150,000/mm^3.[36] In the absence of other hematologic abnormalities, the cause is usually gestational thrombocytopenia, from which the platelet count does not usually decrease to less than 70,000/mm^3. This syndrome is not associated with abnormal bleeding. Gestational thrombocytopenia is due to a combination of hemodilution and more rapid platelet turnover and is a diagnosis of exclusion. Other more consequential diagnoses such as idiopathic thrombocytopenic purpura and hemolysis, elevated liver enzyme, and low platelet count (HELLP) syndrome must be excluded (see section on maternal comorbidities, coagulopathies).

TABLE 62.4 Changes in Coagulation System at Term

PRO-COAGULANT FACTORS	
Increased	I, VII, VIII, IX, X, XII von Willebrand factor
Decreased	XI, XIII
Unchanged	II, V
ANTI-COAGULANT FACTORS	
Increased	None
Decreased	Antithrombin III, Protein S
Unchanged	Protein C
Platelets	Decreased 0%-10%

Thromboelastography (TEG) is a hemostatic assay that measures the kinetics of clot formation and breakdown. It can provide information about clotting variables, including platelet function as well as the function of other coagulation factors (see also Chapter 50). At term gestation, TEG analysis reflects a hypercoagulable state with decreased time to start of clot formation (R), decreased time to specified clot strength (K), increased rate of clot formation (α), and increased clot strength (MA).[37] Although the timing and degree of change in TEG analysis varies with each parameter, many of the changes begin to occur within the first trimester.[38]

NEUROLOGIC CHANGES

Pregnant patients are considered more sensitive to both inhaled and local anesthetics. They have a reduced minimum alveolar concentration (MAC) for inhaled anesthetics. The MAC of a volatile anesthetic is reduced by 40% in animals[39,40] and 28% in humans during the first trimester of pregnancy.[41] However, it appears the decrease in MAC (i.e., immobility in response to volatile anesthetics among 50% of patients) occurs at the level of the spinal cord based on an electroencephalographic study suggesting that anesthetic effects of sevoflurane on the brain are similar in the pregnant and nonpregnant state.[42] The underlying mechanism of reduced MAC in pregnancy remains unclear; it is likely multifactorial, and many postulate progesterone may have a role.

Pregnant women are more sensitive to local anesthetics and neuraxial anesthetic requirements are decreased by 40% by term. At term, the epidural veins are distended and the volume of epidural fat increases, which decreases the size of the epidural space and volume of cerebrospinal fluid (CSF) in the subarachnoid space. Although the decreased volume of these spaces facilitates the spread of local anesthetics, the local anesthetic dose requirement is decreased for neuraxial block as early as the first trimester, before significant aortocaval compression or other mechanical- or pressure-related changes occur.[43] Consequently, the increased nerve sensitivity and decrease in local anesthetic dose requirements are likely biochemical in origin.

Uteroplacental Physiology

The placenta is a remarkable organ that undergoes vast changes from a fertilized ovum's initial implantation into the uterine wall until birth. The placenta is composed of both maternal and fetal tissues and is the interface of maternal and fetal circulation systems. It provides a substrate for physiologic exchange between the two systems. The placenta is made up of a basal and a chorionic plate that are separated by the intervillous space. Maternal blood is delivered to the placenta by the uterine arteries and enters the intervillous space via the spiral arteries. It travels toward the chorionic plate, passing fetal villi where exchange takes place, and then drains back to veins in the basal plate and then ultimately away from the uterus via the uterine veins. The fetal blood arrives at the placenta via two umbilical arteries that form umbilical capillaries that cross the chorionic villi. After placental exchange, oxygen-rich, nutrient-rich, and waste-free blood is returned from the placenta to the fetus through a single umbilical vein.

UTERINE BLOOD FLOW

An understanding of uteroplacental blood flow is critical for appropriate clinical care. Uterine blood flow increases progressively during pregnancy from about 100 mL/min in the nonpregnant state to 700 to 900 mL/min (~10% of cardiac output) at term gestation.[44,45] Approximately 80% of the uterine blood flow perfuses the intervillous space (placenta) and the remainder perfuses the myometrium. Uterine blood flow has minimal autoregulation, and the vasculature remains essentially fully dilated during pregnancy. Uterine and placental blood flow depend upon maternal cardiac output and are directly related to uterine perfusion pressure and inversely related to uterine vascular resistance. Decreased perfusion pressure can result from maternal hypotension secondary to multiple causes including hypovolemia from blood loss or dehydration, decreased systemic resistance from general or neuraxial anesthesia, or aortocaval compression. Increased uterine venous pressure from aortocaval compression, frequent or prolonged uterine contractions, or prolonged abdominal musculature contraction with bearing down (Valsalva) during second-stage pushing can decrease uterine perfusion. Additionally, extreme hypocapnia ($PaCO_2 < 20$ mm Hg) occasionally associated with hyperventilation secondary to severe labor pain can reduce uterine blood flow with resultant fetal hypoxemia and acidosis. Neuraxial blockade does not alter uterine blood flow as long as maternal hypotension is avoided but decreases in maternal blood pressure during neuraxial or general anesthesia should be immediately corrected.

Endogenous maternal catecholamines and exogenous vasopressors may cause increasing uterine arterial resistance and decreasing uterine blood flow depending on the class and amount given. In a pregnant ewe model, use of α-adrenergic vasopressors—methoxamine and metaraminol—increased uterine vascular resistance and decreased uterine blood flow, whereas administration of ephedrine did not reduce uterine blood flow despite drug-induced increases in maternal arterial blood pressure.[46] As a result, ephedrine was previously considered the vasopressor of choice for the treatment of hypotension caused by the administration of neuraxial anesthesia to pregnant women. In complete contrast, more recent human trials demonstrate the use of phenylephrine (α-adrenergic agonist) for prophylaxis or treatment of neuraxial-induced hypotension is not only effective in preventing hypotension, but also is associated with less fetal acidosis and base deficit than the use of ephedrine.[47-50] Other methods to reduce maternal hypotension with induction of regional or general anesthesia are discussed in the section on anesthesia for cesarean delivery.

PLACENTAL EXCHANGE

Oxygen Transfer

The delivery of O_2 from the mother to the fetus depends on a variety of factors, including the ratio of maternal to fetal placental blood flow, the O_2 partial pressure gradient between the two circulations, the diffusion capacity of the placenta, the respective maternal and fetal hemoglobin concentrations and O_2 affinities, and the acid-base status of the fetal and maternal blood (Bohr effect). O_2 delivery to the fetus is facilitated primarily because the fetal oxyhemoglobin dissociation curve is to the left (greater O_2 affinity) of the maternal oxyhemoglobin dissociation curve (decreased O_2 affinity). Fetal hemoglobin has a higher O_2 affinity and lower partial pressure at which it is 50% saturated (P50: 18 mm Hg) compared to maternal hemoglobin (P50: 27 mm Hg). Fetal PaO_2 is normally 40 mm Hg and never more than 60 mm Hg, even if the mother is breathing 100% O_2.[51] Animal studies note that in the face of decreased O_2 delivery, fetal O_2 consumption can be maintained with increased O_2 extraction until the maternal O_2 delivery is approximately 50% of its normal state.[52,53] CO_2 easily crosses the placenta and its transfer from the fetus to the mother is limited by blood flow and not diffusion.

Drug Transfer

Maternal-fetal exchange across the placenta occurs by one of four mechanisms: passive diffusion, facilitated diffusion, transporter-mediated mechanisms, and vesicular transport.[54] Most drugs have molecular weights less than 1000 Daltons and, therefore, cross the placenta by diffusion if the drug is not ionized. The rate of diffusion and peak levels in the fetus depend on maternal-to-fetal concentration gradients, maternal protein binding, molecular weight, lipid solubility, and the degree of drug ionization. The maternal blood concentration of a drug is typically the primary determinant of how much drug will ultimately reach the fetus. Nondepolarizing neuromuscular blocking drugs are ionized, have a high molecular weight, and poor lipid solubility resulting in minimal placental transfer. Succinylcholine has a low molecular weight but is highly ionized and therefore does not readily cross the placenta unless given in large nonclinical doses. Thus during administration of a general anesthetic for cesarean delivery, the fetus or neonate is not paralyzed. Both heparin and glycopyrrolate have minimal placental transfer because they are highly charged. In contrast, placental transfer of volatile anesthetics, benzodiazepines, local anesthetics, and opioids is facilitated by the relatively low molecular weights of these drugs. Dexmedetomidine may cross the placental barrier but is stored within the placenta and transfer to the fetus is reduced.[55] As a general consideration, drugs that readily cross the blood-brain barrier also readily cross the placenta. Therefore most centrally acting general anesthetics cross the placenta and affect the fetus. There is a paucity of evidence on the placental transfer of newer drugs such as liposomal bupivacaine and sugammadex at this time.

Fetal blood is more acidic than maternal blood, and the lower pH creates an environment in which weakly basic drugs, such as local anesthetics and opioids, cross the placenta as nonionized molecules and become ionized in the fetal circulation. Because this newly ionized molecule has more resistance to diffusion back across the placenta, the drug may accumulate in the fetal circulation and reach levels higher than the maternal blood. This process is referred to as “ion trapping.” During fetal distress (fetal acidemia), higher concentrations of these weakly basic drugs can be trapped.[56] High concentrations of local anesthetics in the fetal circulation decrease neonatal neuromuscular tone. Extremely high levels, such as those associated with unintended maternal intravascular local anesthetic injection, result in a variety of fetal effects, including bradycardia, ventricular arrhythmias, acidosis, and severe cardiac depression. Placental transfer and fetal uptake of specific analgesic and anesthetic drugs are detailed later in the sections that discuss methods of labor analgesia and anesthesia for cesarean delivery.

FETAL CIRCULATION AND PHYSIOLOGY

Fetal blood volume increases throughout gestation. Approximately onethird of the fetal-placental blood volume is contained within the placenta.[57] During the second and third trimester, the fetal blood volume is estimated to be approximately 120 to 160 mL/kg of fetal body weight.[58] Thus the total blood volume of a term normal fetus is approximately 0.5 L. Although fetal liver function is not yet mature, coagulation factors are synthesized independent of the maternal circulation. The serum concentrations of these factors increase with gestational age and do not cross the placenta. However, fetal clot formation in response to tissue injury is decreased in comparison to that in adults.

The anatomy of the fetal circulation helps decrease fetal exposure to potentially high concentrations of drugs in umbilical venous blood. Approximately 75% of umbilical venous blood initially passes through the fetal liver, which may result in significant drug metabolism before the drug reaches the fetal heart and brain (first-pass metabolism). Fetal and neonatal enzymatic drug metabolism activities are lower than those of adults, but most drugs can be metabolized. In addition, drugs entering the fetal inferior vena cava via the ductus venosus, thus bypassing the portal circulation and the liver, are initially diluted by drug-free blood returning from the fetal lower extremities and pelvic viscera. These anatomic characteristics of the fetal circulation add to the complexity of maternal-fetal pharmacokinetics.

Labor Progress

Labor begins with the onset of repetitive uterine contractions that result in the dilation of the cervix, thus permitting passage of the fetus from the uterus through the birth canal. In reality, however, preparation for labor may begin several hours or days before active labor with an inflammatory process mediated by cellular infiltration and release of local cytokines that result in softening of the cervix. The signals that orchestrate the onset of spontaneous labor are not precisely known. However, “labor” is the onset of organized, regular uterine contractions that result in progressive cervical dilation and effacement. When spontaneous labor does not occur at an appropriate time, labor may be induced for fetal or maternal indications with various pharmacologic and physical methods.[59]

Labor is a continuous process separated into first, second, and third stages. The first stage of labor begins with regular, painful uterine contractions and includes the change of the uterine cervix from a thick, closed tube to an opening of approximately 10 cm through which the fetus can be expelled. This stage is further divided into a latent phase and an active phase. The second stage of labor begins when the cervix is fully dilated and ends with the birth of the newborn. The third stage of labor is the delivery of the placenta. The time course of the first stage of labor was first studied by Emanuel Friedman who described a sigmoidal relationship between cervical dilation and time (Fig. 62.2*A*). The sigmoidal nature of the relationship has since been challenged in that little evidence exists for a deceleration phase as the cervix approaches complete dilation (10 cm). However, the separation of the first stage of labor into an early slow phase termed *latent labor* and a more rapid phase of active labor has stood the test of time and advances in modeling techniques.[60,61] To account for the contemporary obstetric population including an older maternal age and increased maternal and fetal body sizes, a new labor curve has been proposed after analysis of 62,415 parturients.[62,63] The main difference of the newly proposed curve is when latent labor is considered to transition to active labor. Traditionally, this transition point was 4-cm dilation. However, the new curve proposes active labor beginning at 6-cm dilation in both multiparous and nulliparous parturients (Fig. 62.2*B*).

Labor may be referred to as “abnormal” on the basis of having abnormally slow latent labor, arrest in the active phase, or arrest of descent (failure of stage 2). Dystocia, or abnormal labor, may be a result of inadequate uterine contractions, mismatch of fetal and pelvic size, or abnormal fetal position. The diagnosis of dystocia is based on deviation from normal values derived from populations; however, significant variability exists among individual laboring women. Various demographic and genetic factors contribute to the variability in labor progress.[60,61,64-67] Multiparity is associated with

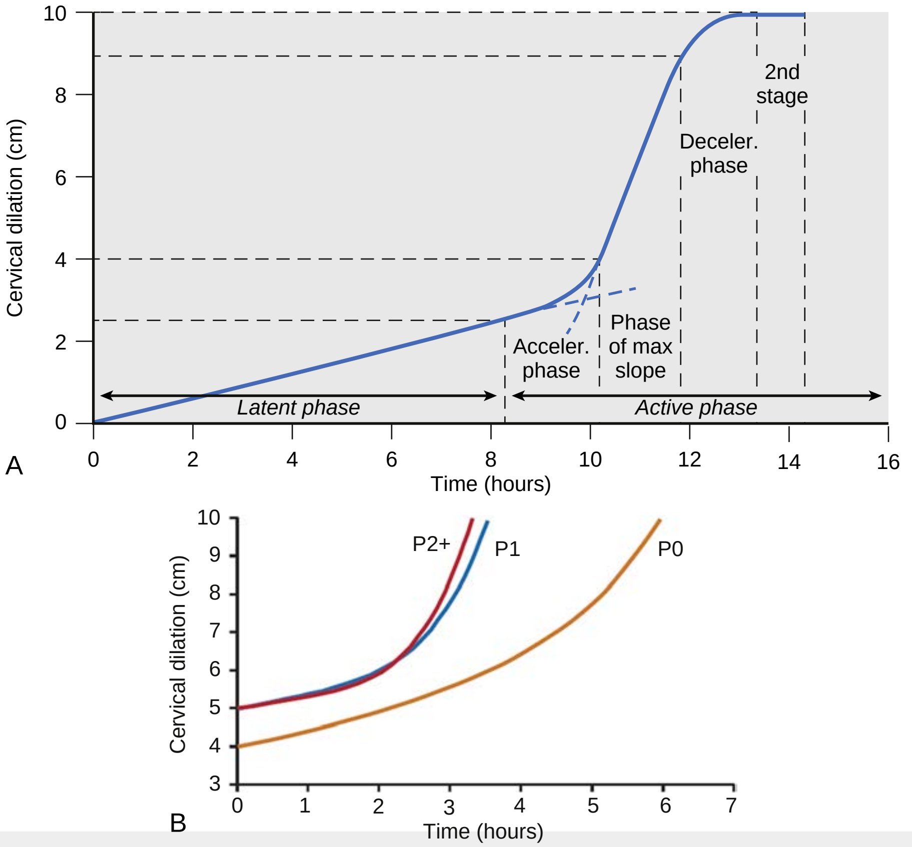

Fig. 62.2 Cervical dilation. (A) Friedman's original sigmoid model of the progress of cervical dilation over time based on an analysis of 500 nulliparas at term. (B) The modern labor curve, which eliminates the deceleration *(Deceler)* phase and changes the threshold for the active phase from 4 to 6 cm. *Acceler,* Acceleration; *P0*, nulliparous women; *P1*, women of parity 1; *P2+*, women of parity 2 or higher. (B) (Legend from Zhang, Fig. 2)Average labor curves by parity in singleton term pregnancies with spontaneous onset of labor, vaginal delivery, and normal neonatal outcomes. Contemporary patterns of spontaneous labor with normal neonatal outcomes. *Obstet Gynecol*. 2010;116:1281–1287. doi: 10.1097/AOG.0b013e318fdef6e.)

faster labor. Greater maternal weight, older age, and larger fetal size have been associated with slower labor.[60,65,68] Evidence also indicates a hereditary role in labor progress from epidemiologic studies.[69] Specifically, β_2-adrenergic and oxytocin receptor polymorphisms have been implicated in mediating variability in labor progress.[64-66] An abnormally poor response to intrinsic or extrinsic oxytocin may result in abnormal contractility, as would an abnormally strong response to β_2-adrenergic agonists (either exogenous or endogenous) which inhibit contractility.

LABOR AND FETAL MONITORING

Intrapartum fetal monitoring was created to evaluate fetal well-being and detect fetal distress earlier in labor to allow intervention prior to permanent fetal injury. Electronic fetal monitoring (EFM) combines interpretation of fetal heart rate (FHR) monitoring and uterine contraction monitoring. FHR monitoring was developed in the 1960s and its use has been increasing since.[70] There is high interobserver and intraobserver variability of FHR tracing interpretation.[71,72] A meta-analysis comparing EFM to intermittent FHR auscultation noted the use of EFM reduced the risk for neonatal seizures (relative risk [RR]: 0.50), but not the risks for perinatal mortality or cerebral palsy.[73] The use of this monitoring has been shown to increase the rate of both operative and cesarean deliveries.[73,74]

The nomenclature, interpretation, and management principles for FHR monitoring were updated in 2009 by the American Congress of Obstetricians and Gynecologists (ACOG).[74] These current guidelines are detailed later, and related terminology is presented in Box 62.1. An understanding of the specific uterine contraction and FHR monitoring terminology as well as the clinical implications is critical for optimal communication during emergent situations among anesthesiologists, obstetricians, midwives, and labor nurses.

CONTRACTION MONITORING

Uterine contractions can be monitored externally with a tocodynamometer or internally with an intrauterine pressure transducer. External monitors only allow determination of contraction frequency, whereas internal monitors also allow quantitative measurement of intrauterine pressure. The Montevideo unit is traditionally used by obstetricians to assess the adequacy of uterine contractions. The Montevideo unit is defined as the intensity of contractions

BOX 62.1 **Fetal Heart Rate Monitoring Pattern Definitions**

Baseline

- The mean FHR rounded to increments of 5 bpm during a 10-min segment, excluding:
    - Periodic or episodic changes
    - Periods of marked FHR variability
    - Segments of baseline that differ by more than 25 bpm
- The baseline must be for a minimum of 2 min in any 10-min segment, or the baseline for that period is indeterminate. In this case, one may refer to the prior 10-min window for determination of baseline.
- Normal FHR baseline: Rate is 110-160 bpm.
- Tachycardia: FHR baseline is greater than 160 bpm.
- Bradycardia: FHR baseline is less than 110 bpm.

Baseline Variability

- Fluctuations occur in the baseline FHR that are irregular in amplitude and frequency.
- Variability is visually quantitated as the amplitude of peak-to-trough in beats per minute.
    - Absent: Amplitude range is undetectable.
    - Minimal: Amplitude range is detectable but 5 bpm or fewer.
    - Moderate (normal): Amplitude range is 6-25 bpm.
    - Marked: Amplitude range is greater than 25 bpm.

Acceleration

- A visually apparent abrupt increase (onset to peak in <30 s) occurs in the FHR.
- At 32 weeks' gestation and beyond, an acceleration has a peak of 15 or more bpm above baseline, with a duration of 15 s or more but less than 2 min from onset to return.
- Before 32 weeks' gestation, an acceleration has a peak of 10 or more bpm above baseline, with a duration of 10 s or more but less than 2 min from onset to return.
- Prolonged acceleration lasts 2 min or more but less than 10 min.
- If an acceleration lasts 10 min or longer, it is a baseline change.

Sinusoidal Pattern

- Visually apparent, smooth, sine wave–like, undulating pattern occurring in FHR baseline, with a cycle frequency of 3-5 cycles/min that persists for 20 min or longer.

bpm, Beats per minute; *FHR,* fetal heart rate.

Data from Macones GA, Hankins GD, Spong CY, et al. The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines. *Obstet Gynecol*. 2008;112:661–666.

(in millimeters of mercury, as measured with an intrauterine pressure catheter) multiplied by the number of contractions that occur in 10 minutes.

Uterine contractions are quantified over a 10-minute window that is averaged over a 30-minute window with guidelines provided by the ACOG.[74] Normal contractions are defined as five or fewer contractions in 10 minutes, averaged over a 30-minute window. Tachysystole is defined as uterine activity greater than five contractions in 10 minutes, averaged over a 30-minute window. Tachysystole applies to both spontaneous and augmented labor and should always be qualified as to the presence or absence of associated FHR decelerations. Treatment of tachysystole during labor may differ depending on the clinical situation but may include sublingual or intravenous nitroglycerin[75] to briefly relax the uterus, as well as the use of β_2-adrenergic drugs such as terbutaline.

FETAL HEART RATE TRACING

FHR monitoring is most commonly accomplished with a surface Doppler ultrasound transducer (external monitoring), but it may be necessary to apply a fetal scalp electrode to obtain accurate continuous FHR monitoring (internal monitoring). For internal monitoring, a peak or threshold voltage of the fetal R wave from the scalp electrode is used to measure FHR. Of note, a fetal scalp electrode can be placed only if the cervix is minimally dilated and the membranes are ruptured. The FHR pattern changes in response to fetal asphyxia from activation of peripheral and central chemoreceptors and baroreceptors.[76] It also shows changes as a result of various fetal brain metabolic changes that occur with asphyxia.[76] These changes in the FHR produce specific patterns and characteristics that provide an evaluation of the fetal state.

The FHR tracing is used as a nonspecific reflection of fetal acidosis. It should be interpreted over a time course in relation to the clinical context and other known maternal and fetal comorbidities, because multiple factors other than fetal acidosis can influence the FHR tracing. Box 62.1 defines FHR baseline, variability, and accelerations. A normal baseline FHR ranges from 110 to 160 bpm. FHR variability are fluctuations in the baseline FHR that are irregular in frequency and amplitude. Normal FHR variability predicts early neonatal health and a fetal central nervous system that is normally interacting with the fetal heart. Accelerations are abrupt changes in the FHR above baseline and are defined by gestational age of the fetus.

Fig. 62.3 details FHR tracing deceleration characteristics. Late decelerations are a result of uteroplacental insufficiency causing relative fetal brain hypoxia during a contraction. The resulting sympathetic outflow elevates the fetal blood pressure and activates the fetal baroreceptors and an associated slowing in the FHR. A second type of late deceleration is from myocardial depression in the presence of increasing hypoxia.[77] Therefore late decelerations are considered worrisome. On the other hand, early decelerations are considered benign and tend to mirror the uterine contraction and are believed to be in response to vagal stimuli, which are often the result of fetal head compression. Variable decelerations are associated with umbilical cord compression. A sinusoidal FHR pattern is associated with fetal anemia and is considered ominous.[78] In general, minimal-to-undetectable FHR variability in the presence of variable or late decelerations is associated with fetal acidosis.[79] Prolonged decelerations (<70 beats/min for >60 seconds) are associated with fetal acidemia and are extremely ominous, particularly with the absence of variability.[80]

FETAL HEART RATE CATEGORIES

A three-tiered FHR category classification system is currently recommended for fetal assessment with the specific criteria for each category outlined in Box 62.2.[74,78] This

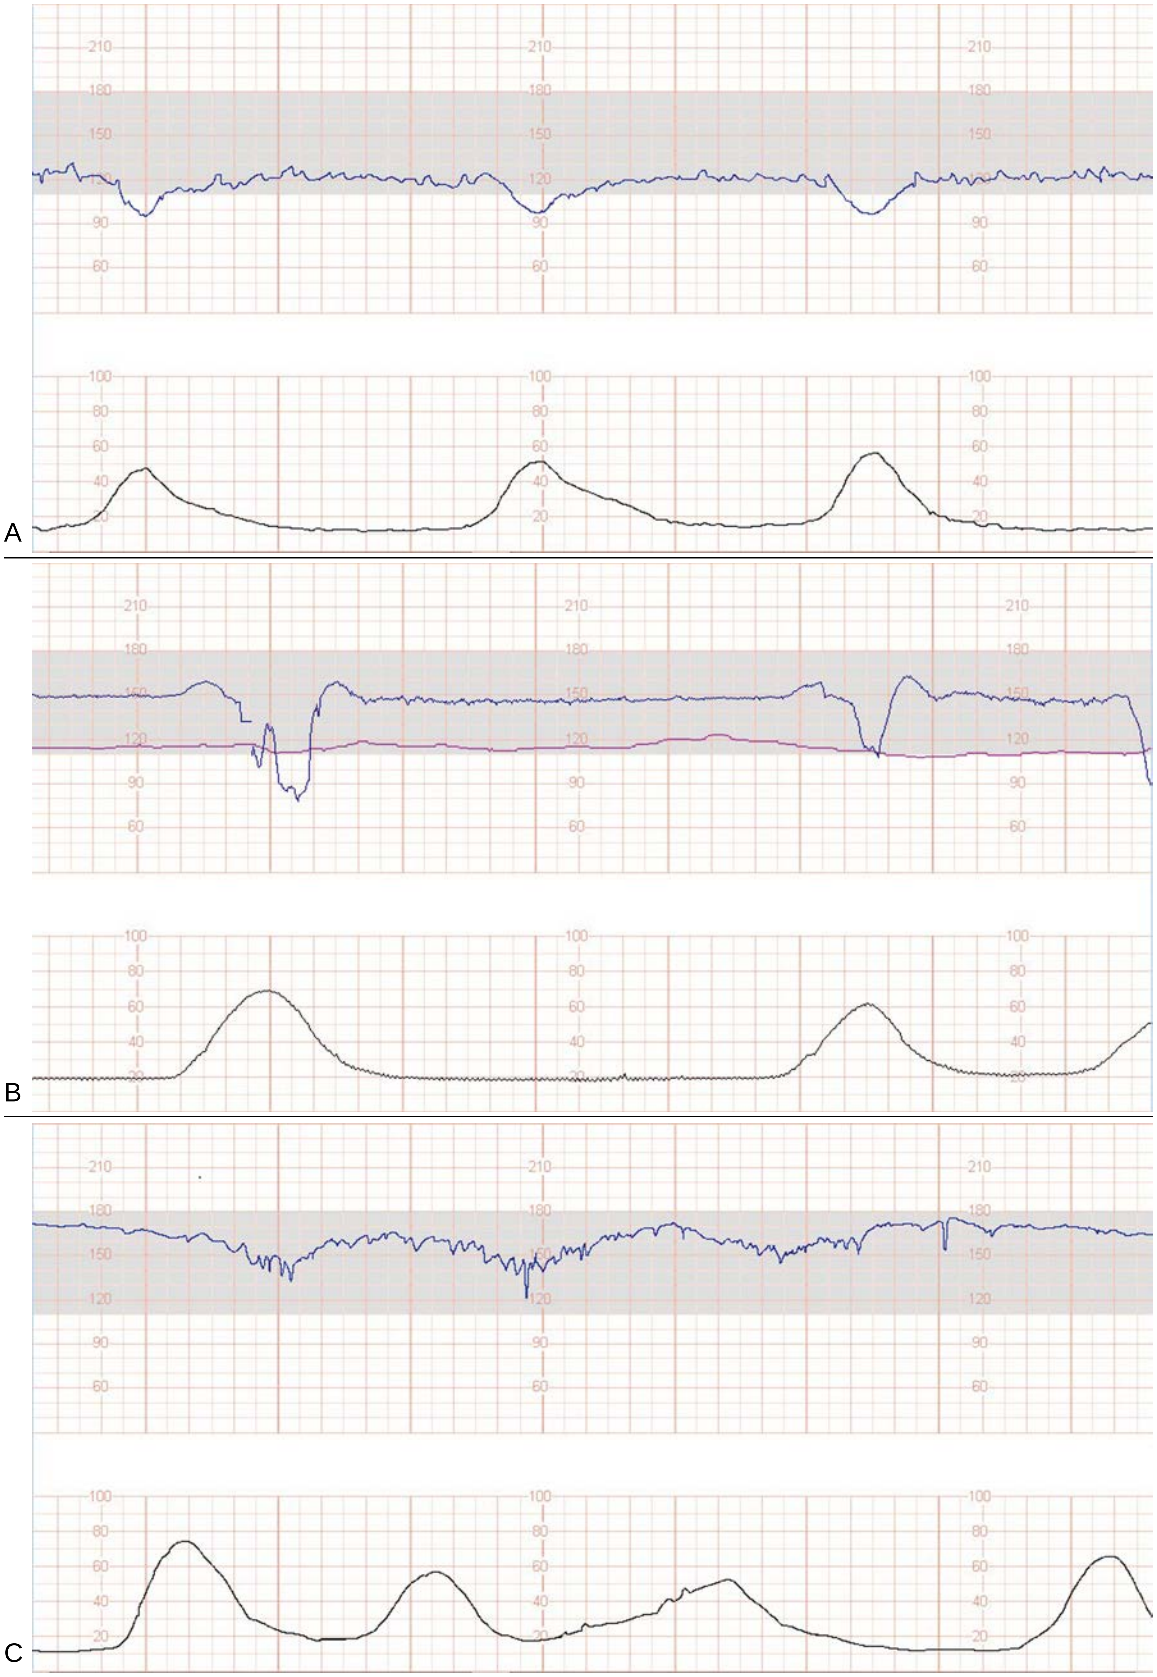

Fig. 62.3 Fetal heart rate deceleration. (A) Early deceleration: visually apparent, usually symmetric gradual decrease and return of the fetal heart rate (FHR) with the nadir of the deceleration occurring at the same time as the peak of the contraction. (B) Variable decelerations: visually apparent, abrupt decrease in FHR ≥15 seconds and <2 minutes. The relationship of the onset of the deceleration compared to the contraction is variable as is the depth and duration. (C) Late FHR decelerations: visually apparent, usually symmetric gradual decrease and return of the FHR during which the nadir of the deceleration occurs after the peak of the contraction.

BOX 62.2 Three-Tier Fetal Heart Rate Interpretation System

Category I

Category I FHR tracings include all of the following:
- Baseline rate of 110-160 beats/min
- Moderate baseline FHR variability
- Late or variable decelerations are absent
- Accelerations and early decelerations may be present or absent

Category II

Category II FHR tracings include all FHR tracings not categorized as Category I or III. Category II FHR tracings may include any of the following:
- Baseline rate:
  - Bradycardia not accompanied by absent baseline variability
  - Tachycardia
- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability with no recurrent decelerations
  - Marked baseline variability
- Accelerations
  - Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
  - Prolonged deceleration ≥2 min but <10 min
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with slow return to baseline, "overshoots," or "shoulders"

Category III

Category III FHR tracings include either:
- Absent baseline FHR variability plus any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

FHR, Fetal heart rate.

Data from Macones GA, Hankins GD, Spong CY, et al. The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines. *Obstet Gynecol.* 2008;112:661–666.

system evaluates the fetus for the given moment of the assessment. The fetal condition may move back and forth among the categories over time. Specific terminology used for categorization is defined in Box 62.1.

Category I FHR tracings are considered normal and are predictive of a normal fetal acid-base state at the time of observation, and no specific management is required.

Category II FHR tracings are considered indeterminate and include all tracings not in categories I or III. Category II tracings are not predictive of abnormal fetal acid-base status and require continued monitoring and reevaluation with consideration for the entire clinical picture. In some cases, additional tests may be obtained or intrauterine resuscitative measures taken to improve the fetal condition.

Category III FHR tracings are considered abnormal and are associated with an abnormal fetal acid-base state at the time of observation. These tracings require prompt patient evaluation and efforts to improve the fetal condition. These interventions may include intrauterine resuscitation with change in maternal position, discontinuation of labor augmentation, treatment of maternal hypotension with fluids and/or vasopressor administration, use of supplemental O_2, and/or administration of a tocolytic agent such as terbutaline. If the FHR tracing does not improve, expeditious delivery should occur which may involve an assisted vaginal (forceps or vacuum) delivery or a cesarean delivery.

Labor Analgesia

Childbirth is a pinnacle event in a family's life that is surrounded by many beliefs and traditions, some of which are founded in science and others more historical, cultural, personal, or even spiritual. In this context, several nonpharmacologic techniques have been used to relieve the pain of childbirth throughout history, including acupuncture,[81] massage,[82,83] and hypnosis.[84] Drugs were not used in Western medicine to relieve pain in childbirth until the mid-1800s, most famously when the English Queen Victoria chose to inhale chloroform for analgesia during the birth of Prince Leopold.[85]

For most women, labor is intensely painful. However, the time course of pain intensity is highly variable, dynamic, and unpredictable. Some women will experience severe pain only just before and during the second stage of labor, whereas others will report severe pain from their first contraction. Rarely do women experience a pain-free labor and give birth unexpectedly under inopportune conditions.[86] The source of these differences in labor pain is not completely known but may be in part genetic. In one study, Asian women reported more pain in labor than women of other ethnic backgrounds.[60] This association was also found with a single nucleotide polymorphism in the β_2-adrenergic gene.[65] Other factors may include parity; maternal pelvic size and shape; fetal size and presentation; maternal anxiety, pain tolerance, and other psychological variables; the presence of maternal social and psychological support during labor; induction of labor; and whether contractions are augmented.

NONPHARMACOLOGIC LABOR PAIN MANAGEMENT

Many patients prefer to use nonpharmacologic methods of pain management during all or part of labor. Acupuncture can be effective in treating postoperative pain after cesarean delivery,[87] but it is not as effective for analgesia during labor. A systematic review and meta-analysis of acupuncture for pain relief in labor involving 10 randomized controlled trials (n = 2038) found that acupuncture was not superior to sham acupuncture (superficial needling lateral to an actual acupuncture point) at 1 and 2 hours.[88] Unfortunately, most of the trials were not properly blinded, increasing the likelihood of bias.

Several trials have found a reduction in pain and anxiety during the first stage of labor with the use of massage. A Cochrane review on massage in labor identified seven randomized trials of massage, six of which were judged to have low or unclear risk for bias.[83] During the first stage of labor, pain was reduced in the massage group by −0.98 (confidence interval [CI], 1.17-0.47) on a 10-point pain scale. No difference was found in the use of pharmacologic pain relief between groups or in pain reported during the second and third stages of labor. Of note, one study of 60 women found that massage decreased anxiety.[89]

Hypnosis has been used both as a relaxation technique and for management of pain during labor. When hypnosis was compared with standard care, no evidence was found that pain was less with the use of hypnosis, nor was evidence found for a difference in satisfaction with pain relief.[83] A Cochrane review of 9 trials randomizing 2954 women found women in the hypnosis group were less likely to use pharmacologic pain relief compared to those in the control groups. There were no clear differences for satisfaction, spontaneous vaginal birth, and postpartum depression between the two groups.[90]

Other nonpharmacologic techniques include the breathing techniques described by Lamaze, the LeBoyer technique, the Bradley method, transcutaneous nerve stimulation, hydrotherapy, presence of a support person, intradermal water injections, and biofeedback. A retrospective national survey of women's childbearing experiences in the United States found that although neuraxial methods of pain relief were considered the most helpful and effective, nonpharmacologic methods of hydrotherapy and massage were rated more or equally helpful in relieving pain compared with the use of intravenous opioids.[91] Although many nonpharmacologic techniques seem to reduce the perception of labor pain, most published studies lack the rigorous scientific methodology for useful comparison of these techniques to pharmacologic methods.

CONSIDERATIONS FOR PHARMACOLOGIC TREATMENT OF PAIN IN LABOR

Preprocedural assessment by an anesthesia provider should be performed for any candidate for neuraxial labor analgesia. Clinical assessment should be considered for all patients admitted to a labor and delivery floor not only to discuss labor analgesia options prior to excruciating pain, but also to assess the patient for comorbid conditions that could complicate labor, obstetric procedures, or anesthesia. The obstetric anesthesia team should be prepared to care for all admitted patients in the event of an obstetric emergency. In otherwise healthy women, laboratory testing is not required during a routine preprocedural obstetric assessment.[92]

Although any laboring woman has the potential to require cesarean delivery, labor takes many hours and requires adequate nutrition and hydration. While balancing these two considerations, the ASA has recommended that moderate amounts of clear liquids be allowed during the administration of neuraxial analgesia and throughout labor. A period of abstention from solids before the placement of neuraxial analgesia is not required. However, the ASA does recommend the ingestion of solid foods be avoided in laboring patients.[92]

SYSTEMIC MEDICATIONS

Opioids can be used for labor analgesia. They are inexpensive, widely available, and can be administered intramuscularly without the need for intravenous access. Although there are differences among opioids, they all cross the placenta and can have fetal effects including dose-related respiratory depression and decreased FHR variability.

Although meperidine was once the most commonly used long-acting opioid in obstetric practice,[93] it is the most likely to result in side effects. Meperidine is typically administered intravenously in doses of up to 50 mg or intramuscularly in doses ranging from 50 to 100 mg. Maternal half-life of meperidine is 2.5 to 3 hours whereas the half-life for its active metabolite normeperidine is 13 to 23 hours. The half-life of both is up to three times longer in the fetus and newborn. Normeperidine can accumulate with repeated doses and can be neurotoxic. With increased dosing and shorter intervals between doses and delivery, risk to the newborn is increased, including lower Apgar scores and prolonged time to sustained neonatal respiration.[94]

Morphine is rarely used for labor pain. Like meperidine it has an active metabolite (morphine-6-glucuronide) with a half-life that is longer in neonates than in adults, and it produces significant maternal sedation. Obstetricians may use intramuscular morphine for analgesia, sedation, and rest. This produces analgesia with an onset of 10 to 20 minutes and is used most commonly in latent labor. Maternal side effects may include respiratory depression and histamine release resulting in pruritus and rash.

Mixed agonist-antagonist opioid analgesics such as nalbuphine and butorphanol are utilized to treat labor pain. Nalbuphine has similar analgesic potency as morphine. It is given either intravenously, intramuscularly, or by subcutaneous injection at doses of 10 to 20 mg every 4 to 6 hours. Butorphanol is five times as potent as morphine and 40 times more potent than meperidine. A dose of 1 to 2 mg intravenously or intramuscularly is commonly used for labor analgesia. Both medications are often well tolerated by the parturient.

Fentanyl and, more recently, remifentanil have become popular systemic opioid analgesics over the past two decades. Fentanyl is a synthetic opioid that is highly lipid-soluble and has a short duration and no active metabolites. When given in small IV doses of 50 to 100 μg/h, no significant differences are seen in neonatal Apgar scores and respiratory effort compared with those in newborns of mothers not receiving fentanyl.[95] Fentanyl is also commonly used in patient-controlled analgesia (PCA) during labor. Common doses utilized for fentanyl PCA include a bolus dose of 10 to 25 μg with a lockout interval of 5 to 12 minutes. High doses of systemic fentanyl, especially immediately prior to birth, could result in neonatal depression.

Remifentanil PCA may offer superior pain relief and lesser fetal effects than other intravenous opioid analgesics but its analgesic effects are inferior to epidural labor analgesia and it requires careful maternal oxygenation and ventilation monitoring. The metabolism of remifentanil depends completely on tissue and plasma esterases, which are fully mature in the fetus. Further, it is more rapidly metabolized in the placenta (by placental esterases) than in the maternal plasma and thus the fetal-to-maternal ratio is small. In the pregnant ewe model, the maternal-to-fetal ratio of remifentanil is approximately tenfold,[96] and the ratio was similar in human studies.[97] Because of these characteristics, more remifentanil can be administered to the mother at times close to delivery than would be considered safe for longer-acting opioids that rely on slower metabolism by the liver. Remifentanil is more effective than long-acting opioids[93]; however, the improvement in pain relief may be because comparatively larger doses of remifentanil were given.[98]

Although remifentanil may be superior to longer acting systemic opioids, it is inferior to epidural labor analgesia. A meta-analysis of randomized controlled trials comparing remifentanil PCA and epidural analgesia found that parturients with remifentanil PCA had higher pain scores at one hour than those who received epidural analgesia.[99] The incidence of pruritus, nausea, and vomiting were not statistically different between the two groups; however, the confidence intervals were wide. A subsequent meta-analysis confirmed that women were less satisfied when receiving remifentanil PCA compared to women in the epidural group but more satisfied than women receiving other parenteral opioids.[100] The major risk of remifentanil in labor is maternal respiratory depression. Careful surveillance is required to ensure adequate oxygenation and ventilation throughout treatment and for this reason, some practices choose not to offer remifentanil PCA labor analgesia.

INHALED ANALGESIA

While volatile anesthetics are no longer used for labor analgesia, nitrous oxide (N_2O) is commonly used worldwide. Typically, it is blended with O_2 in a 50:50 ratio for patient-inhaled self-administration just before and during contractions. A systematic review evaluating N_2O for labor analgesia found that epidural analgesia provided more effective pain relief than N_2O but most studies were of poor quality.[101,102] Some studies have demonstrated moderate analgesia in response to inhaled N_2O (pain scores of 8 in 10 reduced to 6 in 10),[103] whereas others have shown no difference in visual analogue pain scores.[104] Paradoxically, in this negative study, many women wished to continue using nitrous labor analgesia after the study period. Overall, although patients are *less likely* to report excellent pain control with N_2O, they were *as likely* to express satisfaction with their anesthesia care.[102] Therefore although it is less efficacious than neuraxial analgesia, it provides an alternative to patients who desire a less invasive analgesic approach as well as those who have a contraindication for neuraxial analgesia. Without the coadministration of opioids, the use of 50% N_2O in O_2 is safe and does not result in hypoxia or unconsciousness.[105]

NEURAXIAL ANALGESIA

Neuraxial analgesia is the most reliable and effective method of reducing pain during labor.[91] A large meta-analysis found epidural analgesia offered better pain relief compared with placebo (median pain scale reduction 3.4 in 10, 95% CI, 1.3-5.4) and reduced the need for additional pain medication.[106] Analgesia is given most commonly by epidural, spinal, combined spinal-epidural (CSE), or dural puncture epidural (DPE). These techniques provide superior analgesia to alternative approaches and are safe.

Neuraxial Analgesia and Progress of Labor

Considerable controversy has been generated regarding the effects of neuraxial analgesia on the progress of labor. Observational studies have suggested that epidural analgesia is associated with slower labor progress as well as higher cesarean delivery rates.[65,107] Confounding variables are likely responsible for this association. For example, patients who have dysfunctional labor (which are at higher risk to proceed to cesarean delivery) would have more exposure to severe pain, would be more likely to request epidural analgesia, and more likely to request it earlier. Before-and-after studies and multiple prospective, randomized controlled trials have found no association between epidural labor analgesia and cesarean delivery. In fact, a 2011 Cochrane review of 38 studies involving 9658 women comparing epidural versus nonepidural analgesia in labor found no difference in the risk for cesarean delivery.[101] Large prospective studies in which patients were randomly assigned to early or late neuraxial anesthesia have invariably concluded that earlier neuraxial labor analgesia does not affect the length of the first stage of labor or increase the risk for cesarean delivery.[108-112] In contrast, several prospective trials and a meta-analysis suggest that neuraxial anesthesia may cause a modest prolongation of the second stage of labor by approximately 15 minutes.[106,113,114] Increase in the duration of the second stage may occur because dense motor blockade could impede coordinated pushing. Local anesthetic dosing is sometimes reduced in the second stage if the blockade is too dense to allow for coordinated expulsion efforts. However, a recent double-blind trial randomized 400 women with an epidural to either saline or local anesthetic at the onset of the second stage of labor and found no difference in length.[115]

Epidural labor analgesia may offer maternal benefits during the second stage. When labor is comfortable, tolerance for a longer second stage may allow uterine contractions to lower the fetal station before active pushing efforts begin, a technique sometimes called “laboring down.”[116] A large randomized clinical trial of term nulliparous women receiving neuraxial analgesia found no difference in the rate of spontaneous vaginal delivery if they delayed pushing or immediately started pushing at the onset of the second stage.[117] This technique may allow women a less strenuous delivery and can be employed for women with significant comorbid cardiac or vascular conditions to limit the hemodynamic effects of repetitive Valsalva maneuvers. Further, epidural labor analgesia may protect the perineum from injury during delivery by allowing a more controlled expulsion of the fetus that allows for stretching (instead of tearing) of tissues.[118]

Timing of Placement

The optimal timing for the placement of a neuraxial anesthetic has been extensively studied. In 2011, a meta-analysis including prospective, randomized trials was conducted to test if the placement of neuraxial analgesia during the early first stage of labor was associated with a prolonged first stage of labor.[119] Six studies of 15,399 parturients compared placement of neuraxial analgesia at 3-cm cervical dilation or less to placement in active labor.
